The desirability relation $\succsim_D$ is a preordering on N (i.e., $\succsim_D$ is a reflexive and transitive relation). We write $i \succ_D j$ if $i \succsim_D j$ but $j \not\succsim_D i$, and $i \approx_D j$ stands for $i \succsim_D j$ and $j \succsim_D i$. A simple game $\mathcal{W}$ in N is *complete* whenever the desirability relation $\succsim_D$ is total.

A simple game $\mathcal{W}$ in N is a *weighted game* iff there exist nonnegative *weights* $w_1, w_2, \dots, w_n$ allocated to the players and a *quota* $q \in (0, \sum_{i \in N} w_i]$ such that $S \in \mathcal{W}$ iff $\sum_{i \in S} w_i \geq q$. We then write $\mathcal{W} \equiv [q; w_1, w_2, \dots, w_n]$. Any weighted game is complete because $w_i \geq w_j$ implies $i \succsim_D j$. Weighted games are the most frequent real-life voting procedures of simple games.

Complete games have been widely studied. Taylor and Zwicker [15,16] gave respective characterizations of weighted games and complete games in terms of trades among players and within coalitions. In Carreras and Freixas [17] an existence, uniqueness, and classification theorem for complete games was provided that enables us to enumerate all these games up to isomorphism. This theorem also supplies an alternative efficient way to determine, in terms of a set of inequalities, which complete games are weighted. The numbers in Table 1 were obtained using this result, with the exception of weighted games for $n = 9$, which was obtained from Tautenhahn [18].

The sources of real-life examples of complete games are the count and account games or games with consensus (see Peleg [19] and Carreras and Freixas [20] among others).

The weak desirability relation. It was considered by Carreras and Freixas [21]. Let

$\mathcal{W} \in \mathcal{S}_N$ and $i, j \in N$. Define

$$i \succsim_d j \quad \text{iff} \quad |C_i(k)| \geq |C_j(k)| \quad \text{for all} \\ k = 1, 2, \dots, n.$$

A simple game $\mathcal{W}$ in N is *weakly complete* whenever $\succsim_d$, the weak desirability relation on N , is total.

Any complete game is a weakly complete game because $i \succsim_D j$ implies $i \succsim_d j$.

Examples

The three examples below are real-life binary voting games. Example 1 models the first European Economic Community where France, Germany, and Italy were given four votes each, while Belgium and the Netherlands were given two votes and Luxembourg one. Passage required a total of at least 12 of 17 votes. It is an example of a weighted game. Example 2 is not weighted, but complete and is equivalent to an old system to amend the Canadian Constitution ([22] and [23]). Example 3 corresponds to the United States Federal System, which is not complete, but weakly complete. For compelling explanations on these real-life examples, we refer the interested reader to Taylor's book [24].

n	1	2	3	4	5	6	7	8	9
CG	1	3	8	25	117	1171	44,313	16,175,188	284,432,730,174
WG	1	3	8	25	117	1111	29,373	27,30,164	989,913,344

POWER INDICES

We briefly introduce some of the most recognized power indices. The first two are the most distinguished power indices in the literature and are particular cases of semivalues, which are introduced immediately afterward; all of them are weighted sums of the numbers $|C_i(k)|$ when k ranges from 1 to n . For each player $i \in N$, we consider the following power indices.

Shapley–Shubik index. It was introduced by Shapley and Shubik [2] and is the restriction of the Shapley value [3] to simple games (set $|S| = s$ here).

$$\begin{aligned}\phi_i(\mathcal{W}) &= \sum_{S \in \mathcal{C}_i} \frac{(s-1)!(n-s)!}{n!} \\ &= \sum_{k=1}^n |C_i(k)| \frac{1}{\binom{n-1}{k-1} n}.\end{aligned}\quad (1)$$

Apart from the axiomatic treatment we discuss later, the Shapley–Shubik index, as defined in Equation (1), can be given the following heuristic explanation: suppose that the players agree to meet at a specified place and time. Naturally all arrive at different times; it is assumed, however, that all orders of arrival (permutations of the players) have the same probability $\frac{1}{n!}$. Suppose that if a player i arrives and finds the members of the coalition $S \setminus \{i\}$ (and no others) already there, he/she receives 1 as payoff if $S \in \mathcal{C}_i$ and 0 otherwise.

Banzhaf indices (absolute and relative respectively).

$$\beta_i(\mathcal{W}) = \frac{\eta_i(\mathcal{W})}{2^{n-1}}, \quad \beta'_i(\mathcal{W}) = \frac{\eta_i(\mathcal{W})}{\sum_{j=1}^n \eta_j(\mathcal{W})},$$

where the raw Banzhaf index $\eta_i(\mathcal{W})$ is the number of coalitions for which a voter is crucial, that is, $\eta_i(\mathcal{W}) = |\mathcal{C}_i| = \sum_{k=1}^n |C_i(k)|$.

Semivalues as power indices. Semivalues were first introduced in Weber [25] only for simple games and extended to all cooperative games in Dubey *et al.* [26]. There is an interesting characterization of semivalues in terms of *weighting coefficients*, provided by Dubey *et al.* [26] from a group of axioms

for cooperative games. For every weighting vector $p = (p_1, p_2, \dots, p_n)$ such that $p_k \geq 0$ for all $k = 1, \dots, n$ and $\sum_{k=1}^n p_k \binom{n-1}{k-1} = 1$, let ψ be defined by

$$\psi_i(\mathcal{W}) = \sum_{k=1}^n p_k |C_i(k)|$$

for all $i \in N$ and all $\mathcal{W} \in \mathcal{S}_N$. Then ψ is a semivalue. Conversely, any semivalue can be defined in this way, and the correspondence $p \mapsto \psi$ is one-to-one. If p_k is interpreted as the probability that a given player i joins a coalition of size k , provided that all the coalitions of a given size have the same probability of being joined, then, in the case of simple games, $\phi_i(\mathcal{W})$ gives the probability of player i to be crucial under this random scheme, so that it can be interpreted as a measure of this player's expected power.

For example, the Shapley–Shubik index ϕ is defined by weighting coefficients $p_k = 1/\binom{n-1}{k-1}$, and therefore $p_k \binom{n-1}{k-1}$ is constant for all k . The absolute Banzhaf index β is the only semivalue whose weighting coefficients are constant, that is, $p_k = 1/2^{n-1}$ for all k . A *semivalue* ψ is *regular* if $p_k > 0$ for all $k = 1, \dots, n$. In Carreras and Freixas [27] there are characterizations for regular semivalues and for semivalues with binomial coefficients, that is, a semivalue ψ^p is *p-binomial* whenever $p_k = \alpha^{k-1}(1-\alpha)^{n-k}$ for all $k = 1, \dots, n$ and $\alpha \in [0, 1]$. Semivalues have been studied as power indices in Carreras *et al.* [28] and have been applied to real-life situations Refs 27, 29–32.

Johnston index. It was introduced by Johnston [5]. For any winning coalition $S \in \mathcal{W}$, we define $\mathcal{X}(S)$ as the number of elements of S which are crucial for it:

$$\mathcal{X}(S) = |\{j \in S : S \in \mathcal{C}_j\}|$$

and, for each $i \in N$ and each $1 \leq h \leq n$, $\mathcal{C}_i^h$ is the collection of winning coalitions for which voter i and $h-1$ other elements are crucial, that is, $\mathcal{C}_i^h = \{S \in \mathcal{C}_i : \mathcal{X}(S) = h\}$. The raw Johnston is defined as

$$r_i(\mathcal{W}) = \sum_{S \in \mathcal{C}_i} \frac{1}{\mathcal{X}(S)} = \sum_{h=1}^n |\mathcal{C}_i^h| \frac{1}{h}$$

and the Johnston index is

$$\gamma_i(\mathcal{W}) = \frac{r_i(\mathcal{W})}{\sum_{j=1}^n r_j(\mathcal{W})}$$

Note that to measure power the Johnston index equally counts all coalitions with crucial voters and, within each coalition, equally divides power among crucial voters for it.

The indices below are essentially funded by probabilistic approaches.

Rae index. It was introduced in Rae [33] and is based on two assumptions: the votes are independent from one another, and each player votes “yes” with probability 1/2 and votes “no” with probability 1/2.

$$\mathcal{R}_i(\mathcal{W}) = \frac{|\{S : i \in S \in \mathcal{W}\}|}{2^n} + \frac{|\{S : i \notin S \notin \mathcal{W}\}|}{2^n}.$$

The Rae index captures the idea of “success”. It is understood that a voter is satisfied if he/she votes “yes” and the bill is passed or he/she votes “no” and the bill is rejected.

Coleman indices. Coleman [11,34] defines three different indices in terms of different ratios. The first is an index associated to the game and therefore is of different nature to the others. Hence, we do not consider it in the next two sections. The “power of a collectivity to act” measures the ease of decision making by means of a simple game $\mathcal{W}$, and is given by

$$\mathcal{A}(\mathcal{W}) = \frac{|\{S : S \in \mathcal{W}\}|}{|\{S : S \subseteq N\}|} = \frac{|\mathcal{W}|}{2^n}.$$

This notion, extensively treated in Carreras [35], can be used to measure the level of inertia/protectionism of any voting procedure

and to decide whether this level is or not a convenient feature.

Voter i ’s “Coleman index to prevent” action (C_i^P) is given by

$$C_i^P(\mathcal{W}) = \frac{|\{S : i \in S \in \mathcal{W}, S \setminus \{i\} \notin \mathcal{W}\}|}{|\mathcal{W}|} = \frac{\eta_i(\mathcal{W})}{|\mathcal{W}|},$$

while voter i ’s “Coleman index to initiate” action (C_i^I) is given by

$$C_i^I(\mathcal{W}) = \frac{|\{S : i \notin S \notin \mathcal{W}, S \cup \{i\} \in \mathcal{W}\}|}{|2^{N \setminus \mathcal{W}}|}.$$

Brams and Affuso [36] note that Banzhaf and Coleman indices are proportional:

$$\frac{\beta_i(\mathcal{W})}{\sum_{j \in N} \beta_j(\mathcal{W})} = \frac{\beta'_i(\mathcal{W})}{\sum_{j \in N} \beta'_j(\mathcal{W})} = \frac{C_i^P(\mathcal{W})}{\sum_{j \in N} C_j^P(\mathcal{W})} = \frac{C_i^I(\mathcal{W})}{\sum_{j \in N} C_j^I(\mathcal{W})},$$

but this coincidence due to normalization may provoke the loss of their probability interpretation.

König and Bräuninger’s inclusiveness index. It was introduced in König and Bräuninger [37], and it can be understood also as a measure of success.

$$KB_i(\mathcal{W}) = \frac{|\{S : i \in S \in \mathcal{W}\}|}{|\mathcal{W}|} = \frac{|\mathcal{W}_i|}{|\mathcal{W}|}.$$

Computing these power indices by hand for a limited number of voters is quite simple; we provide here the results for Example 1 and the main introduced indices.

$$\phi = \left(\frac{14}{60}, \frac{14}{60}, \frac{14}{60}, \frac{9}{60}, \frac{9}{60}, 0\right), \quad \beta = \left(\frac{5}{16}, \frac{5}{16}, \frac{5}{16}, \frac{3}{16}, \frac{3}{16}, 0\right), \quad \beta' = \left(\frac{5}{21}, \frac{5}{21}, \frac{5}{21}, \frac{3}{21}, \frac{3}{21}, 0\right),$$

$$\gamma = \left(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{8}, \frac{1}{8}, 0\right), \quad \mathcal{R} = \left(\frac{21}{32}, \frac{21}{32}, \frac{21}{32}, \frac{19}{32}, \frac{19}{32}, \frac{16}{32}\right), \quad \mathcal{A} = \frac{7}{32},$$

$$C^P = \left(\frac{5}{7}, \frac{5}{7}, \frac{5}{7}, \frac{3}{7}, \frac{3}{7}, 0\right), \quad C^I = \left(\frac{5}{25}, \frac{5}{25}, \frac{5}{25}, \frac{3}{25}, \frac{3}{25}, 0\right), \quad KB = \left(\frac{12}{14}, \frac{12}{14}, \frac{12}{14}, \frac{10}{14}, \frac{10}{14}, \frac{7}{14}\right).$$

PROPERTIES OF POWER INDICES

We start by considering some properties essentially following Freixas and Gambarelli [38] or Felsenthal and Machover [39]. For any voter $i \in N$, we consider a numerical measure $f_i(\mathcal{W})$ of the power either as voter's expected payoff or as influence.

Efficiency. If we consider power derived from cooperative game theory as expected share in a fixed total prize, then the measure should be *relative*, in the sense that $f_i(\mathcal{W})$ should measure what *share* of the total power of the grand coalition is held by i as compared to all the other voters. Algebraically, the relative character of a measure is expressed by the *efficiency* property:

$$\sum_{i=1}^n f_i(\mathcal{W}) = 1. \quad (2)$$

The indices ϕ, β', γ satisfy efficiency, while $\beta, \psi \neq \phi$ (i.e., any semivalue different from the Shapley–Shubik one) $\mathcal{R}, C^P, C^I, KB$ do not.

Positivity. The monotonicity property required for a simple game also suggests that each individual measure assigned to a voter i must be nonnegative, that is to say the *positivity* property:

$$f_i(\mathcal{W}) \geq 0. \quad (3)$$

All considered indices satisfy positivity. Note that the Rae index and König and Bräuninger's inclusiveness index also satisfy the more restrictive property: $f_i(\mathcal{W}) \geq 1/2$.

Invariance under isomorphism. In order to formulate it we need the following. Let $(N, \mathcal{W})$ and $(N', \mathcal{W}')$ be arbitrary simple games. An *isomorphism* from $(N, \mathcal{W})$ to $(N', \mathcal{W}')$ is a one-to-one mapping g of N onto N' such that, for any coalition $S \subseteq N$, $S \in \mathcal{W} \iff g(S) \in \mathcal{W}'$, where $g(S) = \{g(i) : i \in S\}$. If $(N, \mathcal{W})$ and $(N', \mathcal{W}')$ are isomorphic simple games—that is, if there is an isomorphism from one to the other—then they may be regarded as mere copies of each other, in the sense that they have an identical structure. If g is an isomorphism from $\mathcal{W}$ to $\mathcal{W}'$, then

$$f_i(\mathcal{W}) = f_{g(i)}(\mathcal{W}'). \quad (4)$$

All considered indices satisfy invariance under isomorphism.

Null voter. In a simple game, a null voter ($i \in N$ is *null* if $i \notin S$ for all $S \in \mathcal{W}^m$) has no power, that is to say,

$$f_i(\mathcal{W}) = 0 \quad \text{if } i \text{ is a null voter.} \quad (5)$$

All considered indices satisfy this property with the sole exceptions of $\mathcal{R}$ and KB , which satisfy the analogous property for measures of success rather than decisiveness: $f_i(\mathcal{W}) = 1/2$ for a null voter i . This is because $\mathcal{R}$ and KB are seen as measures of success, while the others are seen as measures of cruciality or decisiveness (see more details in section titled “Probabilistic Approach”).

Some Additional Properties

Let us consider some more properties of power indices that are mainly suggested by their performance on weighted games.

Dominance properties. Consider a weighted game $[q; w_1, \dots, w_n]$. It seems intuitively obvious that if $w_i \geq w_j$ then voter i has at least as much power as voter j , because any contribution that j can make to the passage of a resolution can be equaled or bettered by i . This suggests that any reasonable power index f should be required to satisfy the following condition

$$\begin{aligned} \text{If } \mathcal{W} &\equiv [q; w_1, \dots, w_n] \text{ and} \\ w_i &\geq w_j \text{ then } f_i(\mathcal{W}) \geq f_j(\mathcal{W}). \end{aligned} \quad (6)$$

Two gradually more restrictive versions are

$$\begin{aligned} i \approx_D j, \text{ then } f_i(\mathcal{W}) &= f_j(\mathcal{W}) \quad \text{and} \\ i >_D j, \text{ then } f_i(\mathcal{W}) &> f_j(\mathcal{W}), \end{aligned} \quad (7)$$

$$\begin{aligned} i \approx_d j, \text{ then } f_i(\mathcal{W}) &= f_j(\mathcal{W}) \quad \text{and} \\ i >_d j, \text{ then } f_i(\mathcal{W}) &> f_j(\mathcal{W}), \end{aligned} \quad (8)$$

which are, respectively, named the *D-dominance* and the *d-dominance* properties. It is worth noting that dominance property (6) fails for indices like the Deegan and

Packel [4] or Holler [6] indices, while is satisfied for the other indices considered in section titled “Power Indices”. Only regular semivalues satisfy D -dominance (7) and d -dominance (8). The Johnston index satisfies D -dominance but not d -dominance. The other indices satisfy all three forms of dominance.

Donation. Consider a pair of weighted games, $\mathcal{W}$ and $\mathcal{W}'$, on the same set N whose respective representations have the same quota q and the same total weight ($\sum_{i=1}^n w_i = \sum_{i=1}^n w'_i$):

$$\begin{aligned}\mathcal{W} &\equiv [q; w_1, \dots, w_n], \\ \mathcal{W}' &\equiv [q; w'_1, w'_2, \dots, w'_n].\end{aligned}\quad (9)$$

In this configuration (9), a voter i for which $w_i > w'_i$ is called a *donor* and a voter i for which $w_i < w'_i$ is called a *recipient*. Intuitively, the idea is that $\mathcal{W}$ represents the initial distribution of weights and $\mathcal{W}'$ arises from it by redistribution, the donor “donating” some weight to the recipient; so each donor loses weight and the recipient gains some, while the other weights and the total weight are unchanged. It seems quite unacceptable that the donor gains power; if f is any power index, we say that f satisfies the *donation* property if the following holds in the configuration (9) in which there is a sole donor i and a sole recipient

$$f_i(\mathcal{W}) \geq f'_i(\mathcal{W}') \quad (10)$$

All the indices considered here fulfill the donation (10) property with the exceptions of β' and γ . To see a failure of the donation property consider $\mathcal{W} \equiv [23; 9, 8, 7, 0, 1, 1, 1, 1, 1, 1]$ and $\mathcal{W}' \equiv [23; 8, 8, 7, 1, 1, 1, 1, 1, 1, 1]$. The player with weight 9 in $\mathcal{W}$ becomes the only donor and the player with weight 0 in $\mathcal{W}$ becomes the only recipient in the configuration formed by $\mathcal{W}$ and $\mathcal{W}'$. The relative Banzhaf index β' for the voter with weight 9 in $\mathcal{W}$ is 65/199, while it is 129/392 for the voter with weight 8 in $\mathcal{W}'$. Since $65/199 < 129/392$ the donation property fails. The Johnston index γ for the voter with weight 9 in $\mathcal{W}$ is 173/529, while it is 773/2322 for the voter with weight 8 in $\mathcal{W}'$. Since

$173/529 < 773/2322$ the donation property fails.

Block. Let $\mathcal{W} \in S_N$ and let i and j be distinct voters of N . Taking $i \& j$ to be a new entity, not belonging to N , define a new simple game $\mathcal{W}[i \& j]$ as the collection of all coalitions $S \in (N \setminus \{i, j\}) \cup \{i \& j\}$ satisfying one of the following two conditions: (i) $S \subseteq N \setminus \{i, j\}$ and $S \in \mathcal{W}$; (ii) $S = T \cup \{i \& j\}$ for some T such that $T \subseteq N \setminus \{i, j\}$ and $T \cup \{i, j\} \in \mathcal{W}$.

How should the power of the bloc $i \& j$ in the new simple game compare with the powers of the two components i and j in the original simple game?

At first sight it may perhaps seem reasonable to assume that if i and j are two voters in a simple game $\mathcal{W}$ and j is not null then

$$f_{i \& j}(\mathcal{W}[i \& j]) \geq f_i(\mathcal{W}). \quad (11)$$

This is the *block* property. The bloc $i \& j$ may be regarded as a result of a voluntary merger between voters i and j . A voluntary merger will take place only if, as a result of it, both parties are at least as well off as they were before. But the bloc can equally be regarded as a result of a takeover, in which i , having annexed j 's voting rights, now trades under the new name $i \& j$. Intuitively, it seems inconceivable to us that a voter should not find it beneficial to annex the voting rights of another voter who is not null. Property (11) is a formal statement of this intuition.

All the indices considered here fulfill the block property (11) with the exceptions of β' and γ . To see a failure of these two indices, it will be enough to force a block in the example we took of the donation property; so consider again $\mathcal{W} \equiv [23; 8, 8, 7, 1, 1, 1, 1, 1, 1, 1]$, which we considered for illustrating a failure of the donation property, for β' and γ . Suppose now that a voter with weight 8 and a voter with weight 1 in $\mathcal{W}$ form a block giving rise to the game $\mathcal{W}' \equiv [23; 9, 8, 7, 1, 1, 1, 1, 1, 1, 1]$. Then, the non-null values of both β' and γ for $\mathcal{W}$ (where $\mathcal{W}$ appears in the example of the donation property) coincide with those of $\mathcal{W}'$. Note that the only difference between $\mathcal{W}$ and $\mathcal{W}'$ is that the first is an additional null voter. The failure of the donation property for the two indices provides failure of these indices for the block property.

Transfer. Dubey [7] introduces the following condition. A power index $f: \mathcal{S}_N \rightarrow [0, 1]^n$ satisfies the *transfer* condition if

$$f(\mathcal{W}) + f(\mathcal{V}) = f(\mathcal{W} \cup \mathcal{V}) + f(\mathcal{W} \cap \mathcal{V}). \quad (12)$$

Note that $\mathcal{W} \cup \mathcal{V}$ and $\mathcal{W} \cap \mathcal{V}$ are counterparts of $\mathcal{W}$ and $\mathcal{V}$ and therefore ψ respects the balance of coalitions in both sides of the equality. The indices ϕ , β (and $\mathcal{R}$) and more generally semivalues as power indices satisfy Equation (12). The transfer condition is equivalent to saying that the power index is a *valuation* on the lattice $\mathcal{S}_N$.

Bicameral meet. Suppose that a bill requires the approval of two separate chambers to be passed. Let N_1 and N_2 denote the seats in the two chambers ($N_1 \cap N_2 = \emptyset$), and let $\mathcal{W}_{N_1}$ and $\mathcal{W}_{N_2}$ denote the simple games used by each chamber. Then the bicameral meet based on these two basic simple games is defined by the simple game $\mathcal{W}_N$, with $N = N_1 \cup N_2$, where

$$\mathcal{W}_N = \{S \subseteq N : S \cap N_1 \in \mathcal{W}_{N_1} \text{ and } S \cap N_2 \in \mathcal{W}_{N_2}\}.$$

The *bicameral meet* property requires of a power index f that if i and j are two non-null voters in N_1 then

$$f_i(\mathcal{W}_{N_1})/f_j(\mathcal{W}_{N_1}) = f_i(\mathcal{W}_N)/f_j(\mathcal{W}_N).$$

The two Banzhaf, the two Coleman, and the König and Bräuninger indices satisfy the bicameral meet property, while those of Shapley–Shubik and Johnston fail. Consider the weighted games: $\mathcal{W} \equiv [3; 2, 1, 1]$ and $\mathcal{W}' \equiv [2; 2]$, and $\mathcal{W}'' \equiv [5; 2, 1, 1, 2]$, which is the bicameral meet of the first two. For the Shapley–Shubik index, the yield is $\phi(\mathcal{W}) = (4/6, 1/6, 1/6)$ and $\phi(\mathcal{W}') = (10/24, 2/24, 2/24, 10/24)$. Thus, $\phi_1(\mathcal{W})/\phi_2(\mathcal{W}) = 4$ and $\phi_1(\mathcal{W}')/\phi_2(\mathcal{W}') = 5$. Hence, there is a failure of the bicameral meet property. Similarly, for the Johnston index: $\gamma_1(\mathcal{W})/\gamma_2(\mathcal{W}) = 4$, but $\gamma_1(\mathcal{W}')/\gamma_2(\mathcal{W}') = 3.5$. This example also illustrates a failure of the Rae index. Indeed, $\mathcal{R}_1(\mathcal{W})/\mathcal{R}_2(\mathcal{W}) = 7/5$, but $\mathcal{R}_1(\mathcal{W}')/\mathcal{R}_2(\mathcal{W}') = 11/9$.

AXIOMATIZATIONS VERSUS PROBABILISTIC APPROACH

Some power indices are founded on axiomatizations. An axiomatization for a power index consists of a list of *independent* properties that characterize it as the *unique* power index that satisfies the proposed properties. As more compelling is the list of properties characterizing a given power index, more valuable is the index as a measure of power.

Other power indices are founded on probabilistic approaches. This means that a power index can be interpreted as the probability of a certain event belonging to a sample space related to the game.

The purpose here is to mention some of the main axiomatizations for some of the power indices introduced in section “Power Indices” and to provide a brief probabilistic approach for other indices. A good review on the precise meaning and implications of the power notion in politics can be found in Laruelle and Valenciano [40], wherein many other interesting references on the topic by the same authors are given.

Some Axiomatizations of Power Indices

For lack of space we do not provide any axiomatization, but just mention some of them here, and refer the interested reader to the references. Of course, there exist many other axiomatic characterizations than those cited here.

The Shapley–Shubik index was the first to be characterized. Dubey [7] proves that it is the only map $f: \mathcal{S}_N \rightarrow \mathbb{R}^n$ that satisfies efficiency, anonymity, null player and transfer properties.

Dubey and Shapley [8] provide an adaptation of the characterization by Dubey for the Shapley–Shubik index in order to axiomatize the absolute Banzhaf index by replacing “efficiency” by the following somewhat ad hoc condition (known as *total power property*):

$$\sum_{i=1}^n f_i(\mathcal{W}) = \frac{|\mathcal{C}_i|}{2^{n-1}} \quad (13)$$

to obtain the following result. The absolute Banzhaf index is the only $f: \mathcal{S}_N \rightarrow \mathbb{R}^n$ that

satisfies condition (13), anonymity, null player, and transfer properties.

There is a rich literature on obtaining different axiomatizations of the Shapley–Shubik and the Banzhaf indices; among others, consider Owen [41], Lehrer [42], Roth [43], Straffin [44,45], Haller [46], Feltkamp [47], van der Brink and van der Laan [48], Nowak and Radzik [49], Albizuri [50], and Barua *et al.* [51].

The power indices ϕ and β share three axioms (anonymity, null player, and transfer). These three conditions are also satisfied by all semivalues. The axiomatic characterization given in Weber [52] for this class of games has been adapted to simple games in Carreras *et al.* [28]. Semivalues are basically the family of “values” that result by dropping “efficiency” in Shapley’s characterizing system of the Shapley value. Hence, semivalues for simple games can be seen as “generalized power indices”, and they are uniquely characterized by anonymity, positivity, dummy player, and transfer property.

The Johnston index [5] shares efficiency, null, and anonymity axioms with indices ϕ and β' . Lorenzo-Freire *et al.* [53] characterize it by using a property called *critical mergeability*.

Other relevant relative power indices considered in the literature are the Holler [6] and the Deegan and Packel [4] indices. However, these two indices do not fulfill the domination property in either of its versions: either Equation (6) or Equation (7) or Equation (8). It seems that the failure of domination is a handicap for them. However, they are interesting alternative efficient power indices to those considered here.

In summary, different axiomatizations for an index give different views of it, so that one may find one axiomatization more compelling than the other. In any case, several independent axiomatizations of an index add to its degrees of support as a good measure to evaluate power.

The property of efficiency is a natural and rational condition if the goal is to measure power as an expected payoff (i.e., we want to divide a unit of utility among voters). If we regard power as influence, whatever this might mean, then this condition is not

compelling. None of the measures that we consider in the next section are efficient. There we try to explain power as convenient probability of events rather than with an axiomatic approach.

Probabilistic Approach

Assume that a probability distribution over vote configurations p (exogenous information) enters as a second input besides the simple game $\mathcal{W}$. Of course, $0 \leq p(S) \leq 1$ for all $S \subseteq N$, and $\sum_{S \subseteq N} p(S) = 1$. The probability of i voting “yes” is denoted by $\delta_i(p)$, that is

$$\delta_i(p) = \text{Prob}(i \text{ votes “yes”}) = \sum_{S: i \in S} p(S).$$

In a voting situation thus described by the pair $(\mathcal{W}, p)$, the ease of passing proposals or probability of acceptance is given by

$$\alpha(\mathcal{W}, p) = \text{Prob}(\text{acceptance}) = \sum_{S: S \in \mathcal{W}} p(S).$$

If the proposal is accepted (rejected), those voters who have voted in favor (against) are satisfied with the result, while others are not. We also say that a successful voter has been *decisive* in a vote if his/her vote was crucial, that is, if he/she had changed his/her vote the outcome would have been different.

$$\begin{aligned} \Omega_i(\mathcal{W}, p) &= \text{Prob}(i \text{ is successful}) \\ &= \sum_{S: i \in S \in \mathcal{W}} p(S) + \sum_{S: i \notin S \notin \mathcal{W}} p(S). \end{aligned}$$

$$\begin{aligned} \Phi_i(\mathcal{W}, p) &= \text{Prob}(i \text{ is decisive}) = \sum_{\substack{S: i \in S \in \mathcal{W} \\ S \setminus \{i\} \notin \mathcal{W}}} p(S) \\ &\quad + \sum_{\substack{S: i \notin S \notin \mathcal{W} \\ S \cup \{i\} \in \mathcal{W}}} p(S). \end{aligned}$$

According to Laruelle and Valenciano [40], Barry’s [54] equation for “success” = “decisiveness” + “lucky” remains valid in a much more precise and general version:

$$\Omega_i(\mathcal{W}, p) = \Phi_i(\mathcal{W}, p) + \Lambda_i(\mathcal{W}, p),$$

where $\Lambda_i(\mathcal{W}, p)$ denotes voter i 's "luck" or probability of being "lucky", that is,

$$\Lambda_i(\mathcal{W}, p) = \sum_{\substack{S: i \in S \\ S \setminus \{i\} \in \mathcal{W}}} p(S) + \sum_{\substack{S: i \notin S \\ S \cup \{i\} \notin \mathcal{W}}} p(S)$$

Consider the following notation:

$$\begin{aligned} \Omega_i^+(\mathcal{W}, p) &= \text{Prob}(i \text{ is successful \& } i \text{ votes "yes"}) \\ &= \sum_{S: i \in S \in \mathcal{W}} p(S), \\ \Omega_i^-(\mathcal{W}, p) &= \text{Prob}(i \text{ is successful \& } i \text{ votes "no"}) \\ &= \sum_{S: i \notin S \in \mathcal{W}} p(S), \end{aligned}$$

so that voter i 's probability of success is:

$$\Omega_i(\mathcal{W}, p) = \Omega_i^+(\mathcal{W}, p) + \Omega_i^-(\mathcal{W}, p),$$

and voter i 's probability decisiveness is:

$$\Phi_i(\mathcal{W}, p) = \Phi_i^+(\mathcal{W}, p) + \Phi_i^-(\mathcal{W}, p).$$

Conditional probabilities of success and decisiveness under different conditions are also meaningful. The following questions arise naturally in this context:

Question 1: What is voter i 's conditional probability of success (decisiveness), given that voter i votes in favor of (against) the proposal?

Question 2: What is voter i 's conditional probability of success (decisiveness), given that the proposal is accepted (rejected)?

This makes for eight possible conditional probabilities. A little notation is necessary for variations of the measures: (Ω_i and Φ_i). The superindex " $i+$ " (" $i-$ ") expresses the condition given that i votes "yes" ("no"). So the answers to the first question are given by Ω_i^{i+} , Φ_i^{i+} , Ω_i^{i-} , and Φ_i^{i-} , respectively. The superindex "Acc"("Rej") expresses the condition "given that the proposal is accepted (rejected)". Thus, the answers to the second

question are given by Φ_i^{Acc} , Ω_i^{Acc} , Φ_i^{Rej} and Ω_i^{Rej} , respectively. As an illustration, we formulate two of them explicitly. Voter i 's conditional probability of being decisive given that voter i votes in favor of the proposal, is given by

$$\begin{aligned} \Phi_i^{i+}(\mathcal{W}, p) &= \text{Prob}(i \text{ is decisive} \mid i \text{ votes "yes"}) \\ &= \frac{1}{\delta_i(p)} \sum_{S \in \mathcal{C}_i} p(S). \end{aligned}$$

Voter i 's conditional probability of success, given that the proposal is accepted, is given by

$$\begin{aligned} \Omega_i^{\text{Acc}}(\mathcal{W}, p) &= \text{Prob}(i \text{ is successful} \mid \text{acceptance}) \\ &= \frac{1}{\alpha(\mathcal{W}, p)} \sum_{S: i \in S \in \mathcal{W}} p(S). \end{aligned}$$

The ten different unconditional and conditional probabilities of success and of decisiveness considered so far are summarized in Table 2.

Measurement is based on a probability distribution over vote configurations, but the relevant information for estimating this probability is usually not known. One simplification is to assume that all vote configurations are equally probable *a priori*: $p^*(S) = \frac{1}{2^n}$ for any configuration $S \subseteq N$. For this special unbiased distribution of probability some special relations hold:

$$\Omega_i(\mathcal{W}, p^*) = 0.5 + 0.5\Phi_i(\mathcal{W}, p^*). \quad (14)$$

Unconditional decisiveness and conditional decisiveness, given a positive vote or a negative vote, are indistinguishable:

$$\Phi_i(\mathcal{W}, p^*) = \Phi_i^{i+}(\mathcal{W}, p^*) = \Phi_i^{i-}(\mathcal{W}, p^*).$$

But it is worth remarking that these relationships do not hold in general for $p \neq p^*$. Some "power indices" in the literature can be seen as a particularization of some of the measures just introduced. Indeed,

$$\mathcal{R}_i(\mathcal{W}) = \Omega_i(\mathcal{W}, p^*), \quad \beta(\mathcal{W}) = \Phi_i(\mathcal{W}, p^*),$$

and from Equation 14 it follows that

Table 2. Ten Different Unconditional and Conditional Probabilities of Success and Decisiveness

Condition:	None	i votes “yes”	i votes “no”	Acceptance	Rejection
Success	Ω_i	Ω_i^{i+}	Ω_i^{i-}	Ω_i^{Acc}	Ω_i^{Rej}
Decisiveness	Φ_i	Φ_i^{i+}	Φ_i^{i-}	Φ_i^{Acc}	Φ_i^{Rej}

Table 3. Relationships between “Power Indices” and the Current Probabilistic Model

Condition	None	i votes “yes”	i votes “no”	Acceptance	Rejection
Success	$R_i(\mathcal{W})$	Ω_i^{i+}	Ω_i^{i-}	$KB_i(\mathcal{W})$	Ω_i^{Rej}
Decisiveness	$\beta_i(\mathcal{W})$	$\beta_i(\mathcal{W})$	$\beta_i(\mathcal{W})$	$C_i^P(\mathcal{W})$	$C_i^I(\mathcal{W})$

$$\mathcal{R}_i(\mathcal{W}) = 0.5 + 0.5\beta_i(\mathcal{W}).$$

However, as noticed in Laruelle and Valenciano [40], Equation (14) is not necessarily true if $p \neq p^*$. Therefore, success and decisiveness become unrelated concepts for particular distributions of probability different from p^* . Concerning the different Coleman indices and the König–Bräuninger’s index we have

$$\begin{aligned} \mathcal{A}(\mathcal{W}) &= \alpha(\mathcal{W}, p^*), \quad C_i^P(\mathcal{W}) = \Phi_i^{\text{Acc}}(\mathcal{W}, p^*), \\ C_i^I(\mathcal{W}) &= \Phi_i^{\text{Rej}}(\mathcal{W}, p^*), \quad KB_i(\mathcal{W}) = \Omega_i^{\text{Acc}}(\mathcal{W}, p^*). \end{aligned}$$

Table 3 summarizes these relationships: The Shapley–Shubik index and more generally semivalues are also measures of decisiveness if we consider particular choices of p .

DISCUSSION

In this section, we have two purposes. The first purpose is to summarize the degree of accomplishment of some properties considered in the section titled “Properties of Power

Indices” and to discuss the frequency of some failures of these properties. The second purpose is to analyze the ordinal equivalence of power indices, that is to say, to study whether they rank voters equally.

The occurrence of paradoxes and its frequency. Table 4 summarizes the failures of some properties for some power indices. We use the following notation: decisiveness = $\Phi(\mathcal{W}, p)$; success = $\Omega(\mathcal{W}, p)$; ND: means “not if $p(S)$ dependent on $|S|$ ”; NI: means “not if independence”; NI’: means “not if independence and $\delta_i = \delta_j$ ” for all $i, j \in N$.

Freixas and Molinero have done an experimental analysis that gives us some kind of evidence on whether some of these properties’ (dominance, donation, and bloc) failures are simply occasional facts and so can be regarded as occasional phenomena or, on the contrary, they appear frequently; hence, the term “paradoxical” for the failure of these properties seems to be rather inappropriate. We have found that

For β' and γ and for all games between five and eight voters, the percentage of times that the donation paradox arises is close

Table 4. Testing Several Indices

↓ Property/measure →	Shapley–Shubik (ϕ)	Banzhaf (β')	Johnston (γ)	Decisiveness	Success
D-dominance	Never	Never	Never	ND	ND
d-dominance	Never	Never	May occur	ND	ND
Donation	Never	May occur	May occur	Never	Never
Bloc	Never	May occur	May occur	Never	Never
Bicameral	May occur	Never	May occur	NI	NI

to 3%, whereas for the bloc paradox the percentage is close to 1%.

For β' and γ and for games with a large number of voters both the donation and the bloc paradoxes tend to appear very frequently.

In summary, we have checked that these failures are not isolated facts due to some particularities of the voting system at hand. Given an arbitrary game with a large number of voters, one should expect that these failures will be produced and therefore we should regard these failures as normal rather than as paradoxes. It seems clear that efficiency (Eq. (2)) is a very strong demand for a power index that may cause these failures, and, in fact, it is an unnecessary property when we regard power as an influence. Naturally, decisiveness (and success) behaves better than efficient power indices.

Power indices and their rankings. Of course, different power indices provide different measures and lead to different rankings for the power of voters; in this context a question naturally arises. How different are the separability relations induced by the most well-known power indices?

Let $\mathcal{W} \in \mathcal{S}_N$. Two power indices f and f' are *ordinally equivalent* if their separability relations coincide, i.e., for any $i, j \in N$ the following equivalences hold:

$$\begin{aligned} f_i > f_j &\iff f'_i > f'_j, \\ f_i = f_j &\iff f'_i = f'_j. \end{aligned}$$

Two ordinally equivalent power indices rank players in N in exactly the same way. We say that they induce the same *hierarchy*.

As it was proved in Carreras and Freixas [21], the rankings of voters given by any regular semivalue *coincide* within the class of weakly complete games, which includes almost *all* binary real-life voting systems. In particular, the Shapley–Shubik index and the Penrose–Banzhaf–Coleman indices coincide in weakly complete games. Hence, if we are interested in rankings (qualitative approach) rather than in exact measures (quantitative approach), we regard both the Shapley–Shubik and the Penrose–Banzhaf–Coleman indices as

being *qualitatively equivalent* within weakly complete games. Note, for instance, that the real-life simple games in Examples 1, 2, and 3 are, respectively, weighted, complete, and weakly complete. Hence, for these three classes of games, these indices are ordinally equivalent. Furthermore, the ordinal equivalence of the Shapley and Banzhaf values (or their restrictions for simple games) is still true for a larger class of games called *semicoherent* ([55]). In other words, we have not found any real-life simple game where the rankings for Shapley–Shubik and Banzhaf–Coleman indices do not coincide. So whatever “power” means we find that the most recognized power indices rank voters equally for simple games used in real life.

Another interesting question is to find out which rankings can be induced for regular semivalues. In Freixas and Pons [56], it is proved that all rankings are allowable for these indices inside weakly complete games with the sole exception of the four rankings: $> >$, $> > >$, $= > >$, $= > > >$, which are never available in a simple game.

We finally point out that the Johnston index ranks voters in the same manner as the Shapley–Shubik and Penrose–Banzhaf–Coleman power indices within complete games, and hence it is qualitatively equivalent to them within this class. The Johnston index has also good properties, not discussed here, concerning egalitarianism. We think that the Johnston index (or its raw version, not efficient) is an interesting power index under the shadow of the Shapley–Shubik and Penrose–Banzhaf–Coleman power indices.

MISCELLANEOUS

The section contains some explanations and references about the modification of power indices in the first five sections. In the subsequent sections other issues concerning power indices are treated.

When trying to apply power indices to actual situations, one frequently finds that the personality of the involved agents exerts a great influence in the outcomes. In other words, exogenous relationships must be considered if we do not want to keep the

analysis just in an “*in vitro*” stage but wish to confer to it an “*in vivo*” category, in order to better fit the reality. Curiously, this influence of the agents’ personality is clearly stronger in simple games describing political contexts than in cooperative games describing economic contexts: ideological constraints seem to be much more important in politics than in economics.

Different options have been proposed and used to incorporate additional information into the analysis of games, which is not stored in the characteristic function. Most of them are defined for cooperative games in general, but we emphasize here on its relevance for simple games only. And, of course, the effect of this additional information on the use of power indices is a main point to be considered. Several options are mentioned here: coalition structures, affinities, incompatibilities, cooperation indices, semivalues, partnerships, and persuasion and bribes among others. In some of these cases, the procedure is quite common: the exogenous information gives rise to a restricted game and the original power index is replaced with a modified power index, which is nothing but the original index applied to the restricted game.

Coalition Structures

The notion of coalition structure in a cooperative game was first introduced in Aumann and Drèze [57]. A coalition structure is a partition of the set of players, that is, a family of pairwise disjoint unions that cover the set. The authors argued that the effect of the coalition structure was that of confining the players to play a subgame in each one of the unions. They then defined the modified Shapley value of a game with a coalition structure by assigning to each player his Shapley value in the subgame he is playing within the union he belongs to. No application of this idea to simple games has been developed: the reason is that it very often leads to triviality because most of the unions are, usually, losing coalitions.

However, later on, a different approach that opened a prolific research line, especially on its application to simple games, was given in Owen [58] (also in Ref. 59). The coalition structure induces a quotient game

played by the unions. Then, each union gets the payoff given by the Shapley value in this game. Next, by considering pseudo-quotient games where each subset of a union replaces it in bargaining with the remaining unions and gets a theoretical payoff, we obtain a subgame within each union. By applying again the Shapley value, now to this subgame, the members of that union share its payoff among themselves. This gives rise to the now so-called Owen value. The method applies perfectly to simple games since the subclass they form is closed under the passing to quotient games and subgames. Then a “coalitional Shapley–Shubik index of power” is obtained.

Several applications of this index to real-world political setups have been published. In general, one is interested in discussing which coalition would form, and hence all possible coalition structures are tested using the Owen value. The selected ones, if any, are those that show stability in the very sense of the Nash equilibrium concept: those where no agent (party, nation. . .) possesses incentives to break the coalition structure unilaterally. The case of the Catalonia Parliament [60] illustrates this procedure.

Affinities, Incompatibilities, and Cooperation Indices

In Carreras [61], two main qualitative methods to modify simple games, and hence power indices, were suggested in order to get a better description of real-world situations. The selection of one method or the other will depend in each case on the view that the observer holds on the political relationships, ideological or strategic, among the agents. The former method is based on the affinity idea. A graph describing links between the agents is provided: it is interpreted that only agents connected by a path of links will be able to cooperate among themselves. This implies a modification of the game where only connected minimal winning coalitions are allowed, and one gets a restricted game in this way. Accordingly, the modified Shapley–Shubik power index is defined as the Shapley–Shubik index of the restricted game. This idea, closely related to a similar

work on general cooperative games (Myerson [62]), was applied in Carreras and Owen [60].

The latter method is based on the incompatibility idea and becomes more radical than the former in the sense that, in general, it gives rise to a more drastic modification of the original game. In this case, an irreflexive and symmetrical relation between the agents is assumed to be given, and only the minimal winning coalitions without incompatible members are considered admissible. Again, we get a restricted game and modify the Shapley–Shubik index as discussed earlier.

In Carreras [61], the possibility to combine both methods and simultaneously introduce an affinity graph and an incompatibility relation is also mentioned, without developing, however, the possibilities of this third option.

Nevertheless, a wide generalization, of a quantitative type and hence an increased ability to accurately describe the relationships among the agents, was provided in Amer and Carreras [63] in the general setup of cooperative games by introducing the notion of cooperation index, which encompasses the setup of Myerson [62]. A cooperation index in a game assigns a cooperation degree between 0 and 1 to each coalition. Again, this gives rise to a modified game, and the modified Shapley value is defined as the Shapley value of the modified game. It is worthy of mention that if this technique is applied to a simple game, then a non-simple game may arise as a modified game, so that the modified Shapley–Shubik index is, really, the Shapley value of the modified game.

In Amer and Carreras [64], these ideas are extended to games with a coalition structure and, therefore, yield a modification of the Owen value or power index by means of a cooperation index. Applications to real-world examples can be seen in Amer and Carreras [65,66]. In Amer and Carreras [67] the cooperation index theory is extended to weighted Shapley values (introduced in Kalai and Samet [68]).

Semivalues

Each semivalue is defined by a series of parameters that satisfy certain conditions, and hence the use of semivalues represents an alternative for introducing exogenous

information in the evaluation of games: one need not modify the game but only the viewpoint from which it is analyzed. For instance, the binomial semivalues constitute a special mono-parametric subfamily of semivalues.

Semivalues have been studied as power indices in Carreras *et al.* [28] and have been applied to real-world situations ([27,29–31]). They have been extended to games with a coalition structure in Albizuri and Zarzuelo [69] in the homogeneous case, where a unique semivalue acts in the quotient game and within unions, and in the heterogeneous case, where two arbitrary semivalues are combined.

Partnerships

The notion of partnership was first introduced in Kalai Samet [68] in the setup of weighted Shapley values. In Carreras [70], a detailed study of this concept was carried out, including the possibility to introduce one or more (disjoint) partnerships in a game and obtain a modified game to which any power index can be adapted using the standard method mentioned before. The procedure behaves nicely within the subclass of simple games.

Persuasion and Bribes

Suppose that certain committee is going to decide, using some fixed voting rules, either to accept or to reject a proposal that affects your interests. From your perception about each voter's position, you can make an *a priori* estimation of the probability of the proposal being accepted. Wishing to increase this probability of acceptance before the votes are cast, assume further that you are able to convince (at least) one voter to improve his/her perception in favor of the proposal. The question is: which voters should be persuaded/bribed in order to get the highest possible increase in the probability of acceptance? In other words, which are the optimal persuadable voters? To answer this question, a measure of “circumstantial power” is considered in Freixas and Pons [71]. Three preorderings in the set of voters, based on the voting rules, are defined and they are used

for finding optimal persuadable voters, even in the case that only a qualitative ranking of each voter's inclination for the proposal has been made.

The presidential Election Game and the Power in the European Union

The method of choosing a president for the United States presents a very interesting problem, which is treated in detail in Owen [59] (Chapter XII Section 4). The voters within each state elect "great electors," or members of the Electoral College, who in turn vote for the president. It is generally assumed that all of a given state's electors will vote for whichever candidate is preferred by a majority of the state's voters; thus, a very thin majority in a large state will more than annul large majorities in several small states. Owen analyzes the game from the point of view of both the Shapley–Shubik and Penrose–Banzhaf–Coleman power indices. He did the computations with generating functions and found that for the second index the calculi are considerably simpler since they are based on the square-roots of the census figures. He illustrates that with both indices a voter in California has approximately three times as much power as a voter in the District of Columbia. An observation which is, doubtless, of interest on terms of fairness of the voting system used.

Several binary voting systems have been used in the European Council between 1958 (treaty of Rome) and 2005, the number of members in the Council increasing from 7 to 25. The most complex of these systems are the two established in the treaty of Nice, both of which are complete simple games of dimension 3 ([72]). Several authors have analyzed power in these systems, among them being Bilbao *et al.* [73].

Complexity and Computing Power Indices

Complexity is an interesting issue for all lines of research, and particularly for simple games and power indices. Some easy problems for a small number of voters can become, for a large number of voters, very long processes even for a computer. Hence, it is interesting to determine the complexity of some of

Table 5. Complexity of Changing the Representation Form of a Simple Game

Input → Output ↓	$(N, \mathcal{W})$	$(N, \mathcal{L})$	$(N, \mathcal{W}^m)$	$(N, \mathcal{L}^M)$
$(N, \mathcal{W})$	—	EXP	EXP	EXP
$(N, \mathcal{L})$	EXP	—	EXP	EXP
$(N, \mathcal{W}^m)$	PT	PT	—	EXP
$(N, \mathcal{L}^M)$	PT	PT	EXP	—

these steps. As an example, suppose that we consider four natural ways of representing a simple game: winning, losing, minimal winning, and maximal losing coalitions. The computational cost of passing from one to the other is summarized in Table 5, which is obtained from Freixas *et al.* [74] and where other related problems concerning complexity of simple games are discussed. We use the following notations in the table: $\mathcal{L}$ for the set of losing coalitions of a simple game; PT for polynomial time; EXP for exponential time.

In general, the computation of power indices is NP-hard. And, therefore, a great number of operations are needed even for a computer. Generating functions, see Brams and Affuso [36], are a very useful tool to compute the Banzhaf score and the Shapley–Shubik index (Cantor in 1962 already computed the Shapley–Shubik index in a similar way). Several research groups have developed web pages with their own software to compute power indices; two examples are <http://www.warwick.ac.uk/~ecaae/> and <http://powerslave.val.utu.fi/>.

Dimension and Codimension of Simple Games

Weighted simple games are probably the most important subclass of simple games. It is well known that every simple game can be represented as an intersection of weighted games. It is, nevertheless, of interest to ask how efficiently this can be done for a given simple game. The question of efficiency leads to the definition of *dimension*, [15,16,24]. A simple game is said to be of *dimension* k if and only if it can be represented as the intersection of exactly k weighted games, but not as the intersection of $k - 1$ weighted games. In this sense, we can regard weighted simple games as a generating system of the class

of simple games with the *intersection* as the basic operation.

In Freixas and Marciniak [75], several extensions of the notion of dimension of a simple game are given. The existence of a minimum subclass of weighted games is proved with the property that every simple game can be expressed as its intersection. Some further generalizations lead to the new concept of codimension, which is obtained by considering the union instead of the intersection as the basic operation. Dimension and codimension are significant concepts since most of the real-life binary voting systems are of small dimension or codimension (e.g., the Council of Ministers of the European Union is a system of dimension 3, see details in Ref. 72).

Minimal Integer Representations of Weighted Games

In the section titled “Power Indices,” we have omitted many other power indices regarded as payoffs and which mainly come from cooperative game theory as, for example, the nucleolus, which shares the following properties with ϕ , β' and γ : Equations (2)–(5). There are also set solution concepts like the core or the kernel that may be empty for simple games, but a modification of them, for example, the least core, always gives a nonempty payoff for voters. Some computations have been done on these notions, specially for weighted games or their subclasses. Finding minimal integer representations of weighted games is a twofold interesting problem. On one side, they provide the simplest integer equivalent representation to any arbitrary weighted game, and on the other side these minimal representations are usually related with efficient power indices, see, for example, Peleg [76,77], who proves that the nucleolus of a constant-sum homogeneous weighted game coincides with the unique minimal integer representations of the game. The least core is, in many cases, related to the convex hull of the minimal integer representations of a weighted game.

Isbell in 1959 was the first to find a weighted game *without* a *minimum* integer representation, in which the affected players do not play a symmetric role (i.e., they are not equi-desirable) in the game. His example

has 12 players and is a *weighted decisive* game, that is, a weighted game for which a coalition wins *iff* its complement loses. Quite recently Freixas and Molinero proved in Ref. 78 that the minimum number of voters required to get an example of this type is 9. One of these examples with two minimal representations is formed by the representations: [54; 14, 11, 7, 5, 5, 5, 3, 2, 2] and [54; 14, 12, 6, 5, 5, 5, 3, 2, 2]. Note that the second and third players in such representations are not symmetric (not equi-desirable).

For $n = 8$ voters, there are 154 non-isomorphic weighted games without a unique minimal weight integer realization. For instance, the representations [12; 7, 6, 6, 4, 4, 4, 3, 2] and [12; 7, 6, 6, 4, 4, 4, 2, 3] are equivalent and componentwise minimal. These two equivalent realizations for the game are also equivalent to [14; 8, 7, 7, 5, 5, 5, 3, 3], which preserves types (equi-desirability classes) of players.

Games with Abstention and with Several Levels of Approval

A promising future line of research concerns voting systems with several levels of approval, including abstention or absence. Before dealing with these systems, it is required to provide the basic structure to analyze them. Extensions of simple games, weighted games, desirability, anonymity are important. We refer the reader to Freixas [79] for an appropriate framework dealing with the so-called (j, k) simple games (generalizations of both simple and cooperative games) and weighted (j, k) simple games, to Tchantcho *et al.* [80] for feasible extensions of the desirability relation, to Freixas and Zwicker [81] for anonymous (j, k) simple games, and to Freixas [79,82] for extensions of the Shapley and Banzhaf values.

Acknowledgments

The author wishes to thank Montserrat Pons and Nadezhda V. Smirnova for reading an earlier version of this work and pointing out useful comments that have allowed me to improve the presentation of this brief survey on power indices. I apologize for the omission of many interesting works due to the lack of

space or knowledge. Research was partially supported by Grant MTM 2009–08037 from the Spanish Science and Innovation Ministry, and SGR 2009–1029 of “Generalitat de Catalunya”.

PRESOLVING MIXED-INTEGER LINEAR PROGRAMS

ASHUTOSH MAHAJAN
Mathematics and Computer
Science Division, Argonne
National Laboratory,
Argonne, Illinois

INTRODUCTION

Presolving or preprocessing techniques constitute a broad class of methods used to transform a given instance of a mixed-integer linear program (MILP) or to collect certain useful information about it. The main aim of presolving techniques is to simplify the given instance for solving by the more sophisticated and often time-consuming algorithms such as cutting-plane or branch-and-bound algorithms. Almost all modern solvers, both free [1–4] and commercial [5–7], deploy these in one way or the other. Bixby *et al.* [8] claim that presolving alone speeds the solution times on benchmark instances by a factor of 2. Another important function of a presolver is to analyze the structure of the instance and collect information that will be useful when the problem is solved.

Presolving is also useful for the purpose of modeling, as it can be used to check the instance for obvious errors. It can, for instance, inform the user whether certain constraints or bounds on variables make the instance infeasible or whether certain variables will have arbitrarily high values (unbounded) in a solution. Such information can help the user improve the description of the instance and correct errors. It can also sometimes tell the user whether the values used in the model may cause numerical problems for the subsequent algorithms used by the solver. As such, some presolving is also performed by software such as AMPL [9] that is used for creating MILP instances.

In this article, we describe the various techniques used for basic and advanced

presolving. Throughout the discussion, we assume that the original MILP is of the form

$$\begin{aligned} \min \quad & \sum_{j=1}^n c_j x_j \\ \text{s.t.} \quad & \sum_{j=1}^n a_{ij} x_j \leq b_i, \quad i = 1, \dots, m, \\ & l_j \leq x_j \leq u_j, \quad j = 1, 2, \dots, n, \\ & x_j \in \mathbb{Z}, \quad j \in I, \end{aligned} \quad (\text{P})$$

where $m \in \mathbb{N}$, $n \in \mathbb{N}$, $c \in \mathbb{Q}^n$, $A \in \mathbb{Q}^{m \times n}$, $l \in \mathbb{Q}^n$, $u \in \mathbb{Q}^n$, $I \subseteq \{1, 2, \dots, n\}$ are given as inputs. We will explicitly clarify whenever a technique applies to any equality constraints ($\sum_{j=1}^n a_{ij} = b_i$) and not to the inequalities in Equation (P). Some techniques for presolving MILPs are the same as those used for presolving linear programs (LPs). We also describe these techniques here because they are a starting point for more advanced techniques for presolving MILPs. Most of the presolving techniques presented here are derived from the work of [10–13]. Details of implementing the techniques in an MILP solver can be found in the work of Suhl and Szymanski [14] and Achterberg [15].

We start by describing basic presolving techniques in the section titled “Basic Presolving” and then describe more advanced techniques in the section titled “Advanced Presolving”. We also discuss methods for detecting structure (in the section titled “Identifying Structure”) and for postprocessing (in the section titled “Postsolve”).

BASIC PRESOLVING

Basic presolving methods are simple procedures that are directly applied to simplify Equation (P). These methods may be called many times as subroutines in more advanced methods. Hence, implementing them efficiently is important.

Simple Rearrangements and Substitutions

Removing constraints and variables that are not necessary in the instance can reduce the amount of memory required by a computer to solve the instance and also speed up the calculations. Rearranging the order of variables and constraints in the instance can speed several routines in the subsequent preprocessing and solve methods.

Removing constraints. If we have $a_{ij} = 0 \forall j \in \{1, 2, \dots, n\}$ for some $i \in \{1, 2, \dots, m\}$ and if $b_i \geq 0$, then the i th constraint can be deleted. If for the same constraint $b_i < 0$, then the instance is infeasible because of this constraint. If we have a singleton row, namely, $a_{ik} \neq 0, a_{ij} = 0 \forall j \neq k, j \in \{1, 2, \dots, n\}$, for some $i \in \{1, 2, \dots, m\}$ and some $k \in \{1, 2, \dots, n\}$, then the i th constraint can be removed, and the bounds of variable x_k can be tightened if necessary.

Removing variables. If we have $a_{ij} = 0 \forall i \in \{1, 2, \dots, m\}$ for some $j \in \{1, 2, \dots, n\}$, then we can fix the variable x_j to l_j if $c_j \geq 0$ or to u_j if $c_j < 0$. After fixing the variable, we may have an additional constant term in the objective function. If we have a singleton column x_j , and if $j \notin I$, $a_{ij} > 0$, $l_j = -\infty$, $u_j = \infty$, $c_j \leq 0$ then we can drop the constraint i and substitute $x_j = \frac{b_i - \sum_{k: k \neq j} a_{ik} x_k}{a_{ij}}$ in the objective function. After the substitution, we have one less variable and one less constraint. The number of nonzeros in A is also reduced. The number of nonzeros in the objective function, however, may increase.

Rearrangements. The variables and constraints of the instance can be rearranged depending on how the methods of solving are implemented. For example, it may be beneficial to have all binary variables stored in the end of the array of variables so that deleting them (in case we fix them) from the sparse representation of the matrix A is faster. Similarly, the constraints can be rearranged so that “constraints of interest” appear together in the arrays in which they are stored. If it is known that an interior-point method will initially be used for solving the relaxation of Equation (P), then rows and columns may be

rearranged so as to reduce the “fill in.” Rothberg and Hendrickson [16] study the effects of various such permutation techniques on interior-point methods.

Granularity

Given an instance of form (P) and a vector $\mathbf{a} \in \mathbb{Q}^n$, we define granularity of $\mathbf{a}$ as

$$g(\mathbf{a}) = \min_{x^1, x^2 \in \mathcal{P}} \left\{ \left| \sum_{j=1}^n a_{ij} x_j^1 - \sum_{j=1}^n a_{ij} x_j^2 \right| : \sum_{j=1}^n a_{ij} x_j^1 \neq \sum_{j=1}^n a_{ij} x_j^2 \right\},$$

where $\mathcal{P}$ is the set of all points satisfying the constraints of Equation (P). Granularity refers to the minimum difference (greater than zero) between the values of activity that a constraint or objective function may have at two different feasible points. For a constraint that has only integer-constrained variables, then granularity is at least the greatest common divisor (GCD) of all the coefficients. If any of the coefficients in such a constraint are not integers, we can find a multiplier 10^K , where $K \in \mathbb{Z}^+$, to make all coefficients integers. The GCD can be divided by 10^K to get granularity. Hoffman and Padberg [17] call this procedure Euclidean reduction. The problem can be declared infeasible if there is an equality constraint whose right-hand side is not an integer multiple of the GCD. For an inequality constraint $i \in \{1, 2, \dots, m\}$, if b_i is not an integer multiple of the granularity $g(\mathbf{a}_i)$, then b_i can be reduced to the nearest multiple of g_i less than b_i . So the constraint

$$3x_1 + 6x_2 - 3x_3 \leq 5.3$$

can be tightened to

$$3x_1 + 6x_2 - 3x_3 \leq 3,$$

if $x_1, x_2, x_3 \in \mathbb{Z}$. The bound tightening in this case is a special case of a Chvátal–Gomory inequality introduced by Gomory [18]. Similarly, one can find the granularity of the objective vector $\mathbf{c}$ when only

integer-constrained variables have nonzero coefficients in the objective function. The difference between the upper bound obtained from a feasible solution and the optimal solution value will always be at least $g(\mathbf{c})$. If the difference between an upper bound and a lower bound falls below the granularity, we can stop the branch-and-bound or cutting-plane algorithm and claim that the optimal solution has been found.

Constraint and Variable Duplication

Sometimes, an instance may have duplicate constraints that are exact copies of each other. At other times, we may have constraints that are identical except for a scalar multiple. The obvious benefit of detecting such constraints is that we can reduce the memory needed for storing and solving the instance. It also helps improve the numerical stability of solution of the associated LP relaxations. Bixby and Wagner [19] and Tomlin and Welch [20] describe efficient ways to detect from a column-ordered format of A , whether two constraints are identical except for scalar multiples. When constraints with duplicate entries are found, we can, based on the values of the right-hand sides and the scalar multiples, declare the problem infeasible or delete one of the constraints or combine the two constraints into one.

Similarly, we can detect whether two columns are alike except for a scalar multiple. However, the possible integrality constraint on one or both of these variables can make any substitution complicated. If $A_j = \alpha A_i$ and if $c_j = \alpha c_i$ for some $i, j \in \{1, 2, \dots, n\} \setminus I$, $\alpha \in \mathbb{Q}$, then we can replace the two columns A_i, A_j by a single column A_k that is identical to A_i . The lower and upper bounds of the new variable x_k are $l_k = l_i + \alpha l_j$, $u_k = u_i + \alpha u_j$ if $\alpha > 0$ and $l_k = l_i + \alpha u_j$, $u_k = u_i + \alpha l_j$ otherwise. If one or both variables are integer-constrained, we can use the substitution $x_k = x_i + \alpha x_j$ if we can find feasible values of x_i, x_j for each $x_k \in [l_k, u_k]$. We can also add a constraint $x_k = x_i + \alpha x_j$ to avoid such complications.

Constraint Domination

One way to identify a redundant constraint is to check whether it can be termwise

dominated by another constraint. If $b_k \geq b_i$ for $i, k \in \{1, 2, \dots, m\}$, each variable in constraints i, k is either nonnegative or nonpositive, $a_{kj} \leq a_{ij}$ for j such that x_j is nonnegative and $a_{kj} \geq a_{ij}$ for j such that x_j is nonpositive, then constraint k can be deleted because it is redundant in the presence of constraint i and the bounds on variables.

Bound Improvement

Bound improvement is one of the most important steps of presolving. If we can improve the bounds on variables or reduce b_i , then we can tighten the LP relaxation of Equation (P). The tightest bounds on a constraint can be obtained [13] by solving the following problems:

$$\begin{aligned} \mathcal{L}_i &= \min \sum_{j=1}^n a_{ij}^T x \\ \text{s.t. } A^i x &\leq b^i, \\ l_j &\leq x_j \leq u_j, \quad j = 1, 2, \dots, n \\ x_j &\in \mathbb{Z}, \quad j \in I, \end{aligned} \quad (1)$$

and

$$\begin{aligned} \mathcal{U}_i &= \max \sum_{j=1}^n a_{ij}^T x \\ \text{s.t. } A^i x &\leq b^i, \\ l_j &\leq x_j \leq u_j, \quad j = 1, 2, \dots, n \\ x_j &\in \mathbb{Z}, \quad j \in I, \end{aligned} \quad (2)$$

where the set of constraints $A^i x \leq b^i$ is obtained by deleting the i th constraint $\sum_{j=1}^n a_{ij} x_j \leq b_i$ from Equation (P). However, solving the bound improvement problems 1 or 2 can be as difficult as solving Equation (P). Thus, there is a trade-off between the quality of a good bound and the time spent in finding it. The most common method of tightening the bound is to calculate bounds on $\mathcal{L}_i$ and $\mathcal{U}_i$:

$$\hat{\mathcal{L}}_i = \sum_{j: a_{ij} > 0} a_{ij} l_j + \sum_{j: a_{ij} < 0} a_{ij} u_j,$$

$$\hat{\mathcal{U}}_i = \sum_{j: a_{ij} > 0} a_{ij} u_j + \sum_{j: a_{ij} < 0} a_{ij} l_j. \quad (3)$$

Both $\hat{\mathcal{L}}_i, \hat{\mathcal{U}}_i$ can be calculated in $\mathcal{O}(nz)$ steps, by visiting each nonzero coefficient of the A matrix.

Clearly $\hat{\mathcal{L}}_i \leq \mathcal{L}_i \leq \mathcal{U}_i \leq \hat{\mathcal{U}}_i$. If $b_i < \mathcal{L}_i$, then the instance is infeasible. If $b_i = \mathcal{L}_i$, then all variables appearing in the constraint are forced to a bound: $x_j = l_j$ if $a_{ij} > 0$ and $x_j = u_j$ if $a_{ij} < 0$. This constraint can then be deleted. If $b_i \geq \mathcal{U}_i$, then the constraint can be deleted because it is redundant.

Similarly, we can improve the bounds on variables. The tightest lower and upper bounds for the variable x_k can be obtained by solving the following:

$$\begin{aligned} L_k &= \min x_k \\ \text{s.t. } Ax &\leq b, \\ l_j &\leq x_j \leq u_j, \quad j = 1, 2, \dots, n \\ x_j &\in \mathbb{Z}, \quad j \in I, \end{aligned} \quad (4)$$

and

$$\begin{aligned} U_k &= \max x_k \\ \text{s.t. } Ax &\leq b, \\ l_j &\leq x_j \leq u_j, \quad j = 1, 2, \dots, n \\ x_j &\in \mathbb{Z}, \quad j \in I. \end{aligned} \quad (5)$$

Again, solving the problems (4) and (5) can be as difficult as the original problem (P). A similar trade-off then occurs on the quality of the bound and the time spent in obtaining it. The bounds $\mathcal{L}_i$ and $\mathcal{U}_i$ on constraints can also be used to improve the bounds on variables. If $a_{ik} > 0$, then let

$$\hat{U}_{ik} = \frac{b_i}{a_{ik}} - \frac{\mathcal{L}_i - a_{ik} l_k}{a_{ik}}.$$

Clearly, $\hat{U}_{ik} (\geq U_k)$ is an upper bound on the feasible values of x_k . If $U_k < u_k$ (or $\hat{U}_{ik} < u_k$), then update the bound on variable x_k to U_k . If $U_k < l_k$, then the problem is infeasible. If $U_k = l_k$, then the variable x_k can be fixed to the value l_k . Similarly, if $a_{ik} < 0$, then let

$$\hat{L}_{ik} = \frac{b_i}{a_{ik}} - \frac{\mathcal{U}_i - a_{ik} u_k}{a_{ik}}.$$

Then $\hat{L}_{ik} (\leq L_k)$ is also a lower bound on feasible values of x_k . If $L_k < l_k$, then update the lower bound on variable x_k to L_k . If $L_k > u_k$, then the problem is infeasible. If $L_k = u_k$, then the variable x_k can be fixed to the value u_k . Once $\mathcal{L}_i$ and $\mathcal{U}_i$ (or their bounds $\hat{\mathcal{L}}_i, \hat{\mathcal{U}}_i$) are known, then the bounds $\hat{L}, \hat{U}$ can be calculated in $\mathcal{O}(nz)$ steps.

If the bounds are tightened using the complete models 1 and 2, then constraint domination is just a special case of bound tightening. This is no longer true, however, when the bounds are estimated from each row. In the latter case, we need only $\mathcal{O}(nz)$ calculations, where nz denotes the number of nonzeros in the A matrix.

If the bounds of a variable x_j are implied by a constraint, then the variable can be declared “free”, and we can try substituting the variable out as described in the section titled “Simple Rearrangements and Substitutions.”

Dual/Reduced-Cost Improvement

If, for a variable $x_j, j \in \{1, 2, \dots, n\}$, $a_{ij} \geq 0 \forall i \in \{1, 2, \dots, m\}$, and $c_j \geq 0$, then the variable x_j can be fixed to its lower bound l_j . Similarly, if $a_{ij} \leq 0 \forall i \in \{1, 2, \dots, m\}$ and $c_j \leq 0$, then the variable x_j can be fixed to its upper bound u_j .

Sometimes, an upper bound on the optimal value of solution of Equation (P) is known (it may be provided by the user or may be obtained from some heuristics) before presolving. In such a case, we have an additional inequality $\sum_{j=1}^n c_j x_j \leq z_u$, where z_u is the best-known upper bound. The basic presolving techniques applicable to other constraints can be applied to this constraint as well. Valid inequalities of the form $\sum_{j=1}^n \hat{c}_j x_j \geq z_l$, where $z_l \in \mathbb{Q}$, can also be obtained by linear combinations of the objective function with other constraints. Such inequalities are automatically obtained from the reduced costs calculated by the simplex method. When both z_l and z_u are available as described above, we can do bound tightening on variables to obtain tighter bounds. This is equivalent to the reduced-cost fixing method described by Balas and Martin [21].

ADVANCED PRESOLVING

Advanced presolving procedures try to modify the problem and then call basic preprocessing procedures repeatedly to derive more information about the effects of such changes. Such procedures are also called *probing*. Unlike basic preprocessing techniques, probing may be expensive because one can probe on many possible changes or on combinations of several changes. The simplest changes are the changes of bounds on binary variables. We can fix such a variable to zero or 1 and then probe on the reduced problem.

Fixing Variables

When probing on a binary variable, say x_i , we first fix x_i to zero by changing its upper bound. We then perform basic preprocessing on the modified problem. If the modified problem can be shown to be infeasible, then x_i can be fixed to one in the original problem. Similarly, if the problem becomes infeasible on setting x_i to 1, we can fix x_i to zero. If the problem is infeasible on setting x_i to 1 and zero both, we can declare that the problem is infeasible.

Improving Coefficients

If a constraint i , $\sum_{j=1}^n a_{ij}x_j \leq b_i$ is redundant when a binary variable x_k is set to zero, then we can improve the coefficient a_{ik} of x_k in this constraint using the approach of Crowder *et al.* [22]. We first observe that changing a_{ik} does not make any difference when $x_k = 0$. When x_k is set to 1, the original constraint is equivalent to $\sum_{j=1}^n a_{ij}x_j - \delta_0 x_k \leq b_i - \delta_0$, for any $\delta_0 \in \mathbb{R}$. We would like to have as high a value of δ_0 as possible, while still keeping the constraint redundant at $x_k = 0$. This value of δ_0 can be obtained by solving the following problem:

$$\delta_0 = b_i - \max_Q \sum_{j=1}^n a_{ij}x_j,$$

where Q is the set of values of x such that

$$\begin{aligned} A^i x &\leq b^i, \\ x_k &= 0, \end{aligned}$$

$$\begin{aligned} l_j &\leq x_j \leq u_j, \quad j = 1, 2, \dots, n \\ x_j &\in \mathbb{Z}, \quad j \in I. \end{aligned}$$

Again, the problem of finding the optimal value of δ_0 can be as hard as solving the original problem (P). A more easily computable bound,

$$\hat{\delta}_0 = b_i - \sum_{j:j \neq k, a_{ij} > 0} a_{ij}u_j - \sum_{j:j \neq k, a_{ij} < 0} a_{ij}l_j,$$

can be used instead.

Similarly, if the constraint i , $\sum_{j=1}^n a_{ij}x_j \leq b_i$ is redundant when a binary variable x_k is set to 1, we can replace the constraint by $\sum_{j=1}^n a_{ij}x_j + \delta_1 x_k \leq b_i$, with

$$\delta_1 = b_i - \max_Q \sum_{j=1}^n a_{ij}x_j,$$

where Q is the set of values of x such that

$$\begin{aligned} A^i x &\leq b^i, \\ x_k &= 1, \\ l_j &\leq x_j \leq u_j, \quad j = 1, 2, \dots, n \\ x_j &\in \mathbb{Z}, \quad j \in I. \end{aligned}$$

As above, we can use a bound that is computationally easier to calculate,

$$\hat{\delta}_1 = b_i - a_{ik} - \sum_{j:j \neq k, a_{ij} > 0} a_{ij}u_j - \sum_{j:j \neq k, a_{ij} < 0} a_{ij}l_j.$$

Deriving Implications

Implications are relations that the variable values of any optimal feasible solution must satisfy. One such implication can be found by fixing two binary variables, say, x_i, x_j , where $i, j \in I$ to zero. If the modified problem is shown to be infeasible, then we know that all solutions must satisfy the inequality $x_i + x_j \geq 1$. An equivalent way of looking at this implication is that, if we fix x_i to zero, then x_j is constrained to be 1. A more general case is when fixing x_i to zero implies $x_j = v_j, k \in \{1, 2, \dots, n\}$, where $v_j \in \mathbb{R}$. Then

the following two inequalities are valid for Equation (P):

$$\begin{aligned} x_j &\leq v_j + (u_j - v_j)x_i \\ x_j &\geq v_j - (v_j - l_j)x_i. \end{aligned}$$

Similarly, if by fixing x_i to 1 we can fix x_j to some $v_j \in \mathbb{R}$, then we can write

$$x_i = 1 \Rightarrow x_j = v_j \iff \begin{cases} x_j \leq u_j - (u_j - v_j)x_i, \\ x_j \geq l_j + (v_j - l_j)x_i. \end{cases}$$

When x_j is also binary, we can use the above procedure to obtain the following implications:

$$\begin{aligned} x_i = 0 \Rightarrow x_j = 0 &\iff x_i - x_j \geq 0, \\ x_i = 0 \Rightarrow x_j = 1 &\iff x_i + x_j \geq 1, \\ x_i = 1 \Rightarrow x_j = 0 &\iff x_i + x_j \leq 1, \\ x_i = 1 \Rightarrow x_j = 1 &\iff x_i - x_j \leq 0. \end{aligned}$$

Deriving such implications is useful not only for preprocessing but also for other techniques such as primal heuristics, branching, and generating valid inequalities, which are subsequently used in solving Equation (P). The number of such implications can, however, be very large for certain types of problems. For example, if we have a set partitioning constraint of the form

$$\sum_{i \in S} x_i = 1,$$

where x_i is binary for $i \in S$, then the number of valid implications with only two variables would be $\mathcal{O}(|S|^2)$. Thus it is important to implement methods to store and retrieve them quickly. Several implications can also be combined to fix variables, to delete constraints, and to derive new implications: e.g., if we have implications $x_1 = 0 \Rightarrow x_2 = 0$, and $x_1 = 1 \Rightarrow x_2 = 0$, then we can fix x_2 at 0. Similarly, if a constraint is redundant when $x_1 = 0$ and also when $x_1 = 1$, then we can delete that constraint. The algorithms for deriving such new information from an existing list of implications can be studied with the help of what is called a *conflict graph*.

A conflict graph is a graph that shows what values of binary variables are not

feasible (or optimal) for Equation (P). The graph has two sets $X, \bar{X}$ of k vertices each, where k is the number of binary variables. For each binary variable x_i in Equation (P), we have a vertex each in X (denoted i), and in $\bar{X}$ (denoted $\bar{i}$). A vertex $i \in X$ corresponding to variable x_i is associated with the implication “ $x_i = 1$ ”. Similarly, a vertex $i \in \bar{X}$ is associated with “ $x_i = 0$ ”. An edge between two vertices denotes a conflict, i.e., any optimal solution of Equation (P) cannot have values associated with the two vertices of any edge in the conflict graph. Figure 1 shows a conflict graph in three variables. Three implications that create the edges are $x_1 = 1 \Rightarrow x_2 = 1$, $x_3 = 1 \Rightarrow x_2 = 1$, and $x_3 = 1 \Rightarrow x_1 = 0$. The dark edges in the graph denote that either $x_i = 1$ or $x_i = 0$, and one of them necessarily holds. New implications can now be derived by studying this graph: e.g., if there is a vertex j with neighbors $i, \bar{i}$, then x_j can be fixed to 0. We refer the readers to the work of Savelsbergh and Atamtürk [13] and Savelsbergh [23] for algorithms that can be used to derive such implications. The latter also describe data structures for storing them efficiently. We now mention two more ways in which implications are useful for improving a formulation.

Figure 1. An example of a conflict graph.

Automatic disaggregation. Savelsbergh and Atamtürk [13] show that, if we add the inequalities derived from implications as above, then we automatically disaggregate each constraint of the form

$$\sum_{i \in S} x_i \leq Ux_k,$$

where $S \subseteq \{1, 2, \dots, n\}$, $k \in \{1, 2, \dots, n\}$, and $U \leq \sum_{i \in S} u_i$, into the inequalities

$$x_i \leq u_i x_k, i \in S.$$

Elimination of variables. If fixing a binary variable x_k to zero implies $x_i = r_i$ for some $i \in \{1, 2, \dots, n\}$ and fixing x_k to one implies $x_i = s_i$ for some $r_i, s_i \in \mathbb{R}$, then we can substitute

$$x_i = r_i + (s_i - r_i)x_k.$$

The variable x_i can now be eliminated from the problem without increasing the number of nonzeros in the A matrix.

Probing on Constraints

Consider a clique inequality of the form

$$\sum_{i \in S^+} x_i - \sum_{i \in S^-} x_i \leq 1 - |S^-|,$$

where $S^+, S^- \subseteq \{1, 2, \dots, n\}$, and all x_i are binary for $i \in S^+ \cup S^-$. The tuple $\{x_i\}, i \in S^+ \cup S^-$ can assume only $|S^+ \cup S^-| + 1$ values for any feasible point. Out of these, $|S^+ \cup S^-|$ values correspond to exactly one of $x_i, i \in S^+$ being 1 or exactly one of $x_i, i \in S^-$ being zero. All these cases are therefore considered automatically when probing on these variables. The only remaining case that is feasible for this constraint is when $x_i = 0, \forall i \in S^+$ and $x_i = 1, \forall i \in S^-$. If the problem is infeasible for this case, then the inequality can be tightened to an equality. If some other inequality is redundant, then the coefficients can be tightened following the procedure in the section titled “Improving Coefficients”.

IDENTIFYING STRUCTURE

Many techniques for generating valid inequalities, branching, and heuristics are applicable only for particular types of constraints and variables. Yet others may be greatly improved if some special structures are known to exist. Since such techniques are used repeatedly many times in the branch-and-bound or cutting-plane methods, it is important to detect up front any useful structures in the given MILP. Some of these structures are listed below.

- Special ordered sets of type 1 (SOS1) are of the form

$$\sum_{i \in S} x_i = 1,$$

$$x_k = \sum_{i \in S} a_i x_i,$$

$$x_i \in \{0, 1\}, i \in S \subseteq \{1, 2, \dots, n\}.$$

These can be used for special branching rules [24].

- Set partitioning ($\sum_{i \in S} x_i = \alpha, x_i \in \{0, 1\}, i \in S$), set covering ($\sum_{i \in S} x_i \geq \alpha$), and set packing inequalities ($\sum_{i \in S} x_i \leq \alpha$) can be used for primal heuristics [25] and for generating valid inequalities [26].
- Knapsack inequalities including 0-1 knapsack, mixed 0-1 knapsack, integer knapsack, and mixed-integer knapsack inequalities [27].
- Generalized upper bound constraints can be used to generate valid inequalities [28].
- Variable lower bound and upper bound constraints can also be used to generate valid inequalities [29].

POSTSOLVE

After an instance has been treated by a presolver and then solved, the user may ask for the solution and other problem characteristics. The presolver can change some instances substantially and the solution of the transformed problem may be quite different from that of the original

problem. Hence the presolve routines are designed to save the changes that were made to the original instance. Andersen and Andersen [10] suggest keeping a “stack” of all the transformations that were made by the presolver and reverting them in a last-in-first-out sequence. Sometimes, the solution obtained by reverting the changes may not remain feasible for the specified tolerance values even though the presolved solution was feasible. In such cases, the user must either decrease the tolerance limit or disable presolve.

CONCLUDING REMARKS

In this article, we have surveyed many techniques for presolving. Some of these techniques are simple, like removing empty constraints, and empty columns, identifying special structures and rearranging constraints and variables. Some others are more powerful, like detecting duplicate rows and columns. They require specialized algorithms to avoid spending excessive amount of time. Then there are some methods like bound tightening, detecting infeasibility, and identifying redundant constraints, which in theory can be as difficult as solving the original problem itself. Heuristic methods are used to trade-off the time spent in these problems against the benefits of solving them. All of these methods usually consider only bounds on variables and a single constraint. Advanced presolving methods can help simplifying the problems a lot but each probe requires repeating basic presolving methods. Further, one needs to probe over many candidate variables. In general, it is difficult to predict the optimal effort that should be put into each method of presolving. Most implementations of a presolver rely on several rules of thumb and the past experiences with these methods.

A presolver is an important component of modern MILP solvers. It can substantially reduce the time taken to solve MILPs. It is also useful for conveying to the user obvious problems with the formulation of the instance. However, the percentage of time spent by a solver in presolve routines is usually much smaller than the percentage of

lines of code required to write a presolver. Even though the techniques of presolving are simple, implementing them effectively for all types of formulations and inputs can be a challenging activity.

PRICING AND LEAD-TIME DECISIONS

PELİN PEKGÜN
JDA Software Group,
Marietta, Georgia

In today's increasingly global and competitive marketplace, the demand for goods and services and in turn, the profits of the companies, are not only shaped by their inventory policies and capacity allocation decisions but also by their price and lead-time decisions. For companies that move from a make-to-stock to a make-to-order (MTO) model to satisfy their customers' unique needs, quoting the right price and the reliable lead-time is even more important. Promising an unrealistic due date to an upcoming order may result in monetary penalties as well as diminished prospects for future business. From a firm's point of view, although a shorter lead-time may attract customers and generate more demand, it puts pressure on the firm's production resources with a risk of demand exceeding capacity. On the other hand, customers might be willing to wait longer for their orders if they are offered lower prices. Therefore, depending on its current workload and market conditions, the firm may find it more profitable to offer customers shorter lead-times at the expense of higher prices or vice versa. In this article, we provide an introductory review on monopolistic and competitive models for price and lead-time decisions. The reader should note that papers reviewed in this article are by no means exhaustive. For an extensive review on due date management policies, including simulation-based papers and descriptions of industrial applications, see Keskinocak and Tayur [1]. We also refer the reader to Kaminsky and Hochbaum [2] for a detailed review of analytical models for due date quotations and to Cheng and Gupta [3] for an early survey in this area.

Quoting the right prices and reliable lead-times involves the decisions and actions of both, the marketing and operations/

production functions of a company. In many companies, production is evaluated based on cost and service while marketing is evaluated based on revenue and volume. However, dividing a firm into independent units for performance measurement based on accounting terms often leads to misaligned incentives and suboptimal system performance. In this article, we review studies that assume a centralized decision maker as well as those that assume a decentralized decision making structure and develop coordination mechanisms to align the incentives of marketing and production.

We discuss papers that study monopolistic models in the first section, and those that study the interaction among multiple firms under competition in the section titled "Competitive Setting." Note that within the scope of this article, we refer to the production lead-time and do not consider shipping lead-times. We provide our conclusions in the concluding section.

MONOPOLISTIC SETTING

This section reviews steady-state and dynamic models, where customer demand is a function of the quoted price and lead-time, for the case of a single firm or a single supply chain. We first review models with a centralized decision maker for price and lead-time. At the end of the section, we review decentralized models, where price and lead-time are chosen by different decision makers with different objectives.

Uniform Lead-time Guarantees and Price Decisions

In steady-state models, firm operations are typically modeled as an M/M/1 queue with mean production rate (μ) corresponding to the capacity of the firm and mean arrival rate (λ) corresponding to customer demand. It is shown in Ref. 4 that for high service levels, the exponential distribution provides a close approximation to the tail of the waiting time

distribution even for a G/G/s queue. Thus, the M/M/1 queue assumption makes the problem tractable while the derived results can be perceived as approximately valid for more general demand and service time characteristics. These models develop uniform lead-time guarantees and a single price decision independent of the current state of the system. Moreover, a fixed scheduling rule, such as first-come-first-serve (FCFS), is assumed. Customer demand is modeled as an additive or multiplicative function of price and lead-time.

The additive demand function decreases linearly in the quoted price and lead-time and is of the following form:

$$\lambda = D(p, L) = a - bp - cL. \quad (1)$$

In this equation, a is the total market potential, b is the price sensitivity of demand, c is the lead-time sensitivity of demand, and p and L are the quoted price and lead-time, respectively. As discussed in Ref. 5, the linear demand function has several desirable properties. One desirable property is that both the price elasticity and lead-time elasticity of demand increase in the quoted price and lead-time. This captures the practical observations that customers are more sensitive to the prices they are paying when they have to wait longer, or more sensitive to the waiting times if they are paying higher prices. Note that the Cobb–Douglas demand function, which we will present next, does not exhibit this property. Another desirable property of the linear demand function is the separability of price and lead-time, which reflects customers’ perception of time and money as substitutes, and thus, captures the trade-off between quoted price and lead-time.

Palaka *et al.* [5] study a firm, which serves customer demand that is linearly decreasing in the quoted price and lead-time. The objective of the firm is to maximize total profit. Three types of cost components are considered: variable production costs; congestion-related costs given by the mean number of jobs in the system multiplied by the unit holding cost; and lateness penalty costs incurred as a result of not meeting the quoted lead-times. In order to prevent

unrealistically short lead-times, the authors impose a service-level constraint, which specifies the minimum probability of meeting the quoted lead-time (s):

$$1 - e^{-(\mu - \lambda)L} \geq s. \quad (2)$$

For computational simplicity, a transformation of variables is employed and the service-level constraint is redefined as

$$(\mu - \lambda)L \geq k, \quad (3)$$

where $k = \log(1/(1 - s))$. It is shown that if the service level, s , is at least as large as a certain threshold, which is a function of the price and lead-time sensitivities and lateness penalty, then, the service-level constraint is tight at optimality. In this case, the problem can be transformed into a univariate one in λ for which there exists a unique optimal solution. The authors also consider capacity expansion with a linear expansion cost, and show that whenever the firm is faced with increased inventory holding or lateness penalty costs, higher lead-time sensitivity or service level, the optimal demand rate decreases despite the increase in the optimal capacity.

The following papers use the linear demand function but do not include congestion-related costs or lateness penalty costs in the objective function. They consider capacity expansion as a decision variable, and impose the same service-level constraint, which is shown to be tight at optimality. Ray and Jewkes [6] study a variant of the linear customer demand model in Ref. 5 by treating price as a function of lead-time. Their results show that the lead-time strategy for firms whose customers are more sensitive toward price than lead-time is different from firms whose customers want shorter lead-time and are ready to pay a price premium. The authors also extend this model by incorporating economies of scale, where the unit operating cost is a decreasing function of the demand rate. Boyaci and Ray [7] employ a linear demand function in the case of two substitutable products for which dedicated capacities are allocated:

$$\lambda_1 = a - bp_1 - cL_1 + \beta(p_2 - p_1) + \gamma(L_2 - L_1), \quad (4)$$

$$\lambda_2 = a - bp_2 - cL_2 + \beta(p_1 - p_2) + \gamma(L_1 - L_2). \quad (5)$$

In these equations, β is the sensitivity of switch-overs toward price difference, while γ is the sensitivity of switch-overs toward guaranteed lead-time difference. The lead-time of the standard (slower) product is assumed to be fixed. It is shown that whenever the cost differential is constant, higher marginal capacity costs motivate the firm to differentiate less between the two products, both in price and time, whereas higher cost differentials lead to less time differentiation but more price differentiation. Moreover, ignoring product substitutability can result in higher or lower prices, lead-time, and differentiation, depending on the capacity costs and the market parameters.

As compared to the linear demand approach of the above papers, So and Song [4] use the multiplicative Cobb–Douglas demand function:

$$D(p, L) = ap^{-b}L^{-c}. \quad (6)$$

The log transformation of this function leads to a linear functional form. The price elasticity and lead-time elasticity of demand are constant and directly given by parameters b and c , respectively. Among other results, it is shown that as the capacity of the firm increases, a shorter lead-time should be used, but the direction of the price change depends on the lead-time elasticity of demand. Moreover, optimal lead-time selection is more critical for firms with higher operating costs than those with lower operating costs.

Dynamic Price and Lead-time Quotation

Despite its popularity, there are shortcomings of uniform lead-time guarantees. When demand is high, these lead-times may be understated, leading to missed due dates and disappointed customers, or to higher costs due to expediting. When demand is low, they may be overstated and some customers

may choose to go elsewhere. There are a number of papers that study dynamic price and lead-time quotations taking into account shop-floor congestion for MTO firms, where sequencing decisions are also considered. We refer the reader to the article titled **Pricing and Scheduling Decisions** for an introductory review on pricing and scheduling decisions, and to Ref. 8 for a detailed review on queueing games.

Easton and Moodie [9] treat a tendered bid of price and lead-time decisions as contingent on the firm's future production capacity until the customer makes a decision to accept, reject or modify the firm's bid. The authors use a two-dimensional logit model, based on the contract price and lead-time, to estimate the probability of a successful bid assuming a tardiness penalty if the firm fails to complete the job by the promised date. In order to evaluate this penalty for various lead-times, a model is devised for the probability distribution of the amount of available shop time from the current period to any period in the future, based on the firm's current backlog level. Watanapa and Techanitisawad [10] extend this work and propose a bidding model with multiple customer segments enabling resequencing of orders to accommodate attractive schedules of time-sensitive jobs.

Plambeck [11] models a manufacturer's operations as an exponential single server queue with two classes of customers that differ in their price and lead-time sensitivities. The manufacturer chooses a service rate and a static price for each class of customer, and then dynamically quotes lead-times to potential customers as well as choosing their processing order. The arrival rate for each class decreases linearly with price and lead-time. A policy is proposed such that impatient customers pay a premium for immediate delivery and receive priority in scheduling, while patient customers are quoted a lead-time proportional to the current queue length. Queue length and lead-time are approximated by a reflected Ornstein–Uhlenbeck diffusion process. Celik and Maglaras [12] also use an approximated diffusion control problem to derive near-optimal dynamic pricing, lead-time quotation, sequencing, and expediting policies for the case of an MTO manufacturer

who offers multiple products to a market of price and lead-time sensitive users. Note that in this paper, the firm commits to a lead-time from a set of predetermined lead-times instead of using dynamic lead-time control, and focuses on dynamic pricing for these products.

There is also another stream of research in this area to understand the impact of the delay cost shape on pricing and lead-time decisions. Ata and Olsen [13] consider an MTO firm that dynamically quotes lead-times and prices. Customers are homogenous with the same delay cost function but have nonlinear disutility for the lead-times that they are quoted. As the firm is a monopolist, the problem reduces to one of lead-time quotation and order sequencing. The price for a quoted lead-time is given by the price for the maximum acceptable lead-time plus the customer's delay cost savings for the shorter lead-times. Lead-times are quoted via a shift-based approach and once a lead-time is quoted, it must be met. This approach helps to model the trade-off between committing future capacity beforehand or reserving it for potential higher revenue customers who will arrive later. Using a large-capacity asymptotic regime, the authors provide recommended policies for convex, concave, and convex-concave delay cost functions and prove that these policies are asymptotically optimal. FCFS sequencing is found to be optimal when costs are convex but not necessarily so in other cases. For nonconvex delay cost functions, the convex hull is shown to provide a lower bound for the costs. The general convex-concave, or "S-shaped," cost curve models the case where customers have a particular deadline in mind but once that deadline passes, there is increasingly little difference in the added lead-time. The authors find that in this case, most customers are given relatively short lead-times but a small portion of customers are given very long lead-times as a hedge against demand uncertainty. The numerical studies show that significant benefits can be gained by using the proposed dynamic policies instead of FCFS-based policies. Akan *et al.* [14] extend this work to the nonhomogeneous customer setting, where the firm dynamically

offers menus of prices and lead-times. There are two classes of customers with the same valuation for the product but a different level of patience. Readily implementable policies are proposed for convex-concave delay costs in the context of a large-capacity asymptotic regime. The authors first consider the full information case, where the system manager is aware of the customer types and extracts the entire surplus. On the other hand, under the incomplete information case, where the system manager is unaware of the customer type while offering incentive-compatible menus, achieving the optimal profit under full information depends on how dissimilar the two types of customers are.

Decentralized Decision Making for Price and Lead-Time

So far, we have discussed papers that employ a centralized decision making approach. There are only a few studies that measure the impact of decentralization of price and lead-time decisions. Liu *et al.* [15] consider price and lead-time decisions in a two-firm setting within a supply chain; a supplier and a retailer, where the supplier also needs to choose the transfer price. The authors focus on the inefficiencies that result from the double marginalization in the supply chain and find that decentralization leads to lower profits, higher prices, shorter lead-times, and lower demand. However, they do not consider coordinating mechanisms. A recent paper by Pekgun *et al.* [16] studies a single firm with decentralized marketing and production functions, where marketing is evaluated as a revenue center and production is evaluated as a cost center. Pricing decisions are made by marketing, whereas lead-time decisions are made by production. Since the decentralized settings in the two papers are different, in Ref. 16, decentralization leads to lower profits but lower prices, longer lead-times and higher demand as opposed to the findings in Ref. 15. The authors compare different decision making sequences within the firm and find that a decentralized setting with marketing as the leader dominates one in which production is the leader, particularly for firms operating under tight capacity. It is shown that coordination can be achieved

through a transfer price contract with bonus payments, where marketing pays production a transfer price per unit produced, and both departments receive a fraction of the overall revenue generated as a bonus payment. Note that both Refs 15 and 16 model customer demand as a linear function of price and lead-time in steady state as in Ref. 5.

We conclude the monopolistic setting with a brief discussion on the implications of firm parameters. Under both types of models, higher operating costs imply a higher price and a lower lead-time resulting in lower optimal demand and profit. Additionally, higher capacity implies a lower lead-time but not always a lower price. Although higher capacity implies a higher profit under a centralized structure, Pekgun *et al.* [16] show that it may result in a decrease in profit when marketing is the leader and production is the follower within the organization. Finally, as the service level increases, So and Song [4] show that the price should be reduced to keep the demand under a multiplicative demand model, while Pekgun *et al.* [16] show that the price can be increased up to a certain level, where capacity is sufficient to charge higher for better service, under an additive demand model.

COMPETITIVE SETTING

Most of the research on price and lead-time decisions in steady-state under competition uses queueing models and considers centralized firms. Several researchers employ a “waiting time standard,” which is determined by the time spent in a queue given the allocated capacity. Some researchers aggregate price and waiting time into a “full price” instead of modeling customers’ sensitivity to price and lead-time independently. Loch [17] and Armony and Haviv [18] study two competing service providers with an M/G/1 queue in the former and an M/M/1 queue in the latter and two customer classes, where each class has a distinct waiting cost rate and chooses a provider based on its full price. In Ref. 17, it is shown that the game has a unique Nash equilibrium when firms are symmetric, that is, they have the same

processing time distribution parameters. In Ref. 18, competition is modeled in two stages such that providers compete on the basis of service charges in the first stage, and customer classes compete with allocation decisions in the second stage, where they decide to join or give up the service based on full prices although they cannot observe queue sizes. It is shown that a pure price equilibrium may fail to exist.

Chen and Wan [19] study two M/M/1 service providers that compete for a single customer class on the basis of full price. Providers are differentiated by their service capacities, values of provided service and unit costs of waiting. It is found that the firm with the higher speed or value of service and lower waiting cost charges a price premium, and generates a larger market share when there is a unique equilibrium; however, such a firm may charge lower prices and generate smaller market share and/or lower profit when multiple equilibria exist. Lederer and Li [20] consider N M/G/1 service providers, who compete for N customer classes by choosing prices, production rates, and scheduling policies. They assume that providers are full price takers, and show that Nash equilibrium exists when expected waiting time for a class at a firm is a convex function of the firm’s demand rates for different customer classes. They find that the firm with the faster service, lower variability, and lower cost always generates a larger market share, higher capacity utilization, and profit. This result is accompanied with either higher prices and shorter lead-times, or lower prices and longer lead-times. When customers are differentiated by their demand function and delay sensitivity, competing firms that jointly serve several types of customers match prices and lead-times except for those customers that are the most and least patient (based on their delay costs). While capacity is treated constant in these studies, Cachon and Harker [21] consider the option of outsourcing to a supplier for two competing firms, which experience economies of scale as their unit costs are decreasing in the demand volume. Two types of competition are analyzed: an M/M/1 queueing game with price and

time-sensitive demand, which is modeled as a function of the full prices of both firms in two forms; linear and truncated logit, and an economic order quantity (EOQ) game with fixed ordering costs and price-sensitive demand.

In contrast to the full price approach of the above papers, Allon and Federgruen [22,23] treat price and waiting time independently, where demand decreases in own-price/time effects and increases in cross-price/time effects. Both papers model N M/M/1 firms, the former for a single customer class and the latter for N customer classes. In Ref. 22, the authors use service level, which is defined as the difference between an upper-bound benchmark for waiting time and the firm's actual waiting time standard, whereas in Ref. 23, waiting time is explicitly incorporated into the demand model. Along the same line of research, So [24] extends the work in Ref. 4 to a competitive setting of N M/M/1 firms using a multiplicative competitive interaction model, where the market size is fixed and shared among firms based on their "attraction" given their quoted prices and lead-times. It is shown that the equilibrium solution in the case of identical firms behave in a similar fashion as the optimal solution in the monopolistic firm setting in Ref. 4. On the other hand, if the firms in the market are nonidentical, then, these firms will exploit their distinctive firm characteristics to differentiate their services, where the high-capacity firms provide better lead-time guarantees, and firms with lower operating costs offer lower prices. The differentiation becomes more intense as demand becomes more lead-time sensitive.

A recent work by Pekgun *et al.* [25] extends the work in Ref. 16 and studies centralized and decentralized decision making comparatively for price and lead-time decisions under competition at steady state. The problem is modeled as a two-stage game. In the first stage, firms simultaneously choose their organizational structures to operate in centralized or decentralized mode. In the second stage, they simultaneously choose their price and lead-time decisions. Under decentralization, the price and lead-time strategy is established through a Stackelberg

game, where marketing first sets the price as the leader and then production sets the lead-time as the follower. The authors find that under intense price competition, where the intensity is characterized by the underlying parameters of market demand, firms may suffer from a decentralized structure. This finding has the most impact under high flexibility induced by high capacity, where revenue-based sales incentives motivate sales/marketing for more aggressive price cuts resulting in eroding margins. On the other hand, low-cost firms may benefit from a decentralized structure without hurting margins as long as the intensity of price competition is less than the intensity of lead-time competition. The authors also find that higher capacity does not always result in higher profits under competition even if it comes for free.

CONCLUSIONS

In this article, we have provided an introductory review on price and lead-time decisions, both in monopolistic and competitive settings. In the monopolistic setting, we first reviewed the papers that study uniform lead-time guarantees and price decisions at steady state, where firm operations are typically modeled as an M/M/1 queue. Extensions to general queueing models and multiple product/customer types (particularly under shared capacity) are still open for future research. Given the shortcomings of uniform lead-time guarantees since the steady-state results (e.g., the service-level constraint) may not always hold in the day-to-day operations of a firm, we discussed papers that study dynamic price and lead-time quotations taking into account shop-floor congestion and incorporating sequencing decisions. Extensions in this area for assemble-to-order or make-to-stock systems are potential areas for future research. We also reviewed recent work on the impact of the form of delay cost function on price and lead-time decisions, which is a fairly new area and can be further investigated with more detailed customer modeling and for the impact of competition. Next, we discussed papers that

study decentralized decision making for price and lead-time decisions and the inefficiencies that arise as compared to a centralized structure. We are not aware of any papers that study the impact of decentralization for multiplicative demand models or for dynamic price and lead-time quotations, which can be considered for future research. Finally, we reviewed papers on price and lead-time decisions under competition. While the existence of an equilibrium usually depends on the problem structure and certain conditions, it is possible to observe insights consistent with the monopolistic setting in most cases. However, there does not exist much work yet for dynamic models under the presence of competitors with a centralized or decentralized organizational structure, which can be attributed to the analytical complexity encountered in identifying an equilibrium solution and proving whether the solution is unique.

There is also an increasing body of literature within the marketing/operations interface that addresses the strategic role of production lead-time and its effects on a firm's pricing policies as well as decisions on the lag between when to produce and when to sell. Desai *et al.* [26] discuss that uncertainty about the length of the lead time or about the level of market demand can significantly affect a firm's pricing and production decisions. In a two-period model, they focus on demand uncertainty and production lead time such that the firm has to commit to a specific production quantity before demand is realized. Thus, the firm needs to decide on the production quantities for each period as well as how much to market in the first period, given that customers that purchase the product in the first period can resell it in the second period. This is also a potential area that can be pursued for future research.

PRICING AND REPLENISHMENT DECISIONS

FERNANDO BERNSTEIN
Fuqua School of Business,
Duke University, Durham,
North Carolina

INTRODUCTION

An important problem in the interface between marketing and operations is the simultaneous determination of pricing and inventory replenishment decisions. Traditional inventory models focus on effective replenishment strategies and generally assume that demand for a product is independent of the product's price. In these models, the demand process and all revenue streams are exogenously determined. Marketing models, on the other hand, focus on pricing strategies and their impact on sales and revenues but, for the most part, overlook the firms' inventory decisions.

In recent years, a number of papers have focused on the integration of pricing decisions and inventory replenishment strategies. These decisions have traditionally been made by separate divisions within the organization. However, firms are increasingly pursuing more integrative approaches to manage their inventory and pricing strategies.

This article reviews some of the most significant results regarding the joint determination of pricing and inventory replenishment decisions. There is a vast literature addressing dynamic pricing issues in settings where selling must stop after a deadline and there is no inventory replenishment throughout the selling season. This includes papers focusing on clearance and markdown pricing. Many of these papers have applications to revenue management problems, particularly those pertinent to retail operations. We refer to the section titled "Pricing and Revenue Management" in this encyclopedia and

the book by Talluri and Van Ryzin [1] for extensive reviews of revenue management models. With the exception of single-period models, in which there is a one-time pricing and inventory decision, our focus is on situations in which inventory can be replenished frequently throughout the time horizon.

The papers discussed in this article analyze pricing and inventory decisions for both the case of a single firm and the case of multiple firms. In settings with multiple firms, the article reviews models in which firms operate in nonoverlapping markets (so each retail firm is a monopolist in its own market) and models in which firms compete for demand in the downstream market. The article is organized according to this distinction. The section titled "Single Firm" reviews work related to decisions made within an organization (i.e., the case of a single firm). The next section looks at broader supply-chain management settings in which multiple independent firms make decisions regarding their prices and replenishment strategies. The final section concludes the article. The review in this article is by no means exhaustive. Chan *et al.* [2] and Yano and Gilbert [3] provide excellent survey chapters reviewing models that address the coordination of pricing policies with inventory management and production decisions. In addition, the survey by Chan *et al.* provides a comprehensive taxonomy for work in this field. The article by Alon *Pricing and Scheduling Decisions*, [4] provides a review on work related to pricing and scheduling decisions.

SINGLE FIRM

This section reviews single-period, finite-horizon, and infinite-horizon inventory models in which demand is endogenously determined by a price p . In all these settings, a firm stocks a product in anticipation of uncertain demand. At the same time, the firm can affect demand by determining the

selling price. Joint pricing and replenishment models generally assume that the price-sensitive stochastic demand is of the multiplicative form or of the additive form, while demand randomness is independent of the selling price. In its more general form, demand is given by

$$D(p, \epsilon) = \gamma(p)\epsilon + \delta(p), \quad (1)$$

where ϵ is a random variable independent of price, and $\gamma(p)$ and $\delta(p)$ are nonincreasing functions of p . When $\delta(p) = 0$, demand is of the multiplicative form, and when $\gamma(p) = 1$, demand is of the additive form. In addition to the selling price, the firm decides on a stocking quantity q (or order-up-to level y , so that the order quantity is given by $y - x$ if x is the initial inventory at the beginning of the period in a multiperiod setting).

In a single-period setting, the firm makes a stocking decision for a product that becomes obsolete at the end of the selling period. Any demand in excess of the stocking quantity is lost. [The problem of determining an order quantity in a single-period setting with random demand is sometimes called the *newsvendor problem*. For a review on the newsvendor model, we refer to the article by Petruzzi *Newsvendor Models*, [5].] In addition, the firm decides a selling price for the product over this selling period. The one-period expected profit function is given by $\Pi(q, p) = pED(p, \epsilon) - cq - G(q, p)$, where c is the per unit purchasing or production cost, $pED(p, \epsilon)$ is the expected revenue assuming that all demand is satisfied, and $G(q, p) = h^+E[q - D(p, \epsilon)]^+ + (p + h^-)E[D(p, \epsilon) - q]^+$ is the expected inventory cost function that depends on the order quantity q and on the price p . (Note that $[z]^+ = \max\{z, 0\}$.) Here, h^+ represents the cost of disposing of any left-over inventory at the end of the period and h^- is the penalty cost associated with each unit of unsatisfied demand.

Whitin [6] was the first to consider the price-setting newsvendor problem. In Whitin's model, the probability distribution of demand depends on the selling price, and the price is itself a decision variable. Petruzzi and Dada [7] provide a comprehensive review of the single-period problem in

which a stocking quantity and selling price are set simultaneously. The paper examines the cases of additive demand and multiplicative demand. In both cases, the paper shows properties of the expected profit function that facilitate the optimization of the price and order-quantity variables. The cases of additive and multiplicative demand differ in how the price affects demand variability. Under additive demand, the variance of demand is independent of the selling price, while the coefficient of variation of demand (standard deviation/mean) increases in the price. On the other hand, in the case of multiplicative demand, the coefficient of variation is independent of the price, but the variance is a decreasing function of price. This distinction affects the way in which the selling price is used to mitigate the risk of demand uncertainty, that is, the risks of overstocking (ending the selling period with excess inventory) or understocking (causing lost sales). In the case of additive demand, it is possible to reduce the coefficient of variation of demand by selecting a lower price. This does not affect demand variance. When demand is of the multiplicative form, a firm can decrease demand variance, without affecting the coefficient of variation of demand, by selecting a higher price. Therefore, the paper concludes that a pricing strategy aimed at reducing supply and demand mismatches must depend on the way that price affects the demand function.

Initial work on the simultaneous choice of prices and replenishment strategies in multiperiod settings was confined to the case of price-dependent deterministic demand. In a multiperiod stochastic setting, Thowsen [8] studies the problem of integrating pricing and replenishment decisions under specific forms of the demand function. The paper proposes a heuristic model for a setting without fixed ordering costs. Thomas [9] considers a periodic review, finite-horizon model with fixed ordering costs and stochastic, price-dependent demand. The paper proposes a policy, referred to as (s, S, p) , under which inventory is replenished according to an (s, S) policy and the price depends on the initial inventory level at the beginning of the period.

An (s, S) policy stipulates that if the inventory position at the beginning of the period is below a reorder point s , then an order is placed to raise the inventory position to the order-up-to level S .

Federgruen and Heching [10] address simultaneous pricing and replenishment decisions in periodic review models (both finite and infinite horizons) with stochastic, price-dependent demand. The paper characterizes the structure of the optimal dynamic pricing and inventory strategy for a general stochastic demand function as in Equation (1). In their model, there are no fixed costs for placing orders and all unsatisfied demands are backlogged. One form of the one-period expected inventory and backlogging cost considered in the paper is given by $G(y, p) = h^+ E[y - D(p, \epsilon)]^+ + h^- E[D(p, \epsilon) - y]^+$, with y the order-up-to level, h^+ the per unit holding cost rate, and h^- the per unit backlogging penalty cost rate. The optimal dynamic pricing and inventory policy is a so-called base stock list price policy, characterized by a base stock level y_t^* and list price p_t^* for each period t . If the initial inventory level in period t , x_t , is below the base stock level, then the firm places an order for the difference $y_t^* - x_t$ and charges the list price. Otherwise, the firm places no order in that period and charges a discounted price to increase sales. This result is extended to the infinite-horizon setting with stationary parameters. The paper reports the results of a numerical study that suggests that there are significant benefits to using a dynamic pricing policy, as opposed to a fixed price policy. It is also noted that an increase in the coefficient of variation leads to higher optimal prices. This finding is consistent with the observations regarding the role of the pricing strategy in a single-period setting.

The work by Federgruen and Heching was extended to a setting in which there are both, a fixed cost for placing an order and a variable cost that is proportional to the amount ordered. Chen and Simchi-Levi [11] identify a dynamic inventory policy and pricing strategy that maximizes the expected profit over a finite horizon. As in Federgruen and Heching, this model assumes that unsatisfied demand

in a period is backlogged. The paper also considers demand functions as in Equation (1), with general forms of $\gamma(p)$ and $\delta(p)$. In the case of additive demand, the paper shows that the (s, S, p) policy identified in [9] is indeed optimal. The paper provides separate treatment for the case of multiplicative demand, for which an (s, S, p) policy may fail to be optimal. For the general demand model, the paper shows that the optimal policy is of the form (s, S, A, p) . In each period t , A_t is a (possibly empty) set of initial values of the inventory level. Under this policy, the firm places an order if the inventory level at the beginning of a period t is below s_t or if it is in the set A_t . In either case, an order is placed to raise the inventory level up to the target value S_t . In those cases, the firm charges a list price p_t^* . For all other initial inventory levels, no order is placed and the optimal price depends on the initial inventory level.

Huh and Janakiraman [13] use an alternative approach to prove the optimality of the (s, S, p) policy in a setting with additive demand and fixed ordering cost, both under the backordering and lost sales assumptions. This approach, based on a property related to the single-period expected profit function, can be used to show that the (s, S, p) policy is optimal under more general forms of the demand function. Song *et al.* [12] study the case of multiplicative demand functions, also in the context of lost sales and in settings in which the firm incurs a fixed cost for placing orders. The paper establishes the optimality of the (s, S, A, p) policy in this setting.

Deng and Yano [14] consider the problem of making pricing and production quantity decisions in a finite-horizon setting for a firm facing capacity constraints. The paper assumes that both variable and fixed setup costs are present in the model. Demand is a deterministic downward sloping function of price. The paper characterizes the optimal joint pricing and replenishment policy and shows that optimal prices may increase as the capacity increases.

A number of papers study the problem of jointly determining prices and inventory replenishment decisions for a firm selling multiple products. In a single-period newsvendor setting, Aydin and Porteus [15]

investigate the optimal prices and inventory levels for multiple products. The products' prices affect the overall size of the market and the way in which demand is allocated among products. Under certain classes of demand functions, the paper shows that there is a unique vector of prices and inventory levels that satisfy the first-order optimality conditions. Zhu and Thonemann [16] consider a firm selling two products over a finite horizon. The demand for each product depends on both products' prices. Demands are of the additive form with linear cross-price effects. The paper shows that a base stock list price policy is no longer optimal in this setting. Instead, they show how prices and order quantities can be computed optimally. The paper shows that both the products' prices and the replenishment decisions depend on the initial inventory levels of the two products.

MULTIPLE FIRMS

This section describes research addressing joint pricing and replenishment decisions in settings with multiple firms. These models generally consider two-echelon supply chains. In those settings, a manufacturer or supplier sells a product to one or multiple retail firms that, in turn, offer this product to the market. The retail firms may be geographically dispersed, in which case they do not directly compete in the downstream market, or they may engage in price or quantity competition. In either case, a firm's demand function decreases in its own price. In a competitive setting, a firm's demand increases with increases in the prices of its competitors.

There are two primary decision making paradigms that are analyzed and compared in the multiple-firm setting. Under centralized control, all pricing and replenishment decisions are made by a central planner who has control over the decisions made by all the firms in the supply chain. In contrast, in a decentralized system, each firm makes the pricing and inventory decisions that optimize its own performance, irrespective of the impact that these decisions may have on the

other firms in the supply chain. Competition among firms is inherent to decentralized supply-chain settings. This competitive interaction is modeled and analyzed using tools of Game Theory. We refer to the section titled "Foundations and Principles of Game Theory" in this encyclopedia and the book by Fudenberg and Tirole [17] for comprehensive treatments of this area of study.

In addition to the distinction between centralized and decentralized control, the papers in this section differ in terms of the type of demand functions they consider (e.g., deterministic or stochastic) and in terms of the relevant operational costs present in the system. The various assumptions about the decision making paradigm, the demand functions, and the cost structure, lead to very different dynamics regarding the firms' pricing and inventory replenishment decisions. In particular, in settings with multiple competing retailers, the analysis of equilibrium pricing and replenishment strategies depends on the specific forms of the underlying demand and cost functions. Most papers investigating decentralized supply chains also explore the design of coordinating contracts. These contractual agreements induce firms in the decentralized supply chain to adopt pricing and inventory replenishment strategies equal to those that would be adopted under centralized control, thus leading to higher system-wide profit. We refer to the article by Zhang *Supply Chain Coordination*, [18] for a review of issues related to supply-chain coordination.

Single or Multiple Geographically Dispersed Retailers

The paper by Zhao and Wang [19] studies joint pricing and production decisions in a supply chain consisting of a manufacturer distributing its product through a single retailer or distributor. This firm faces a price-dependent deterministic demand. The paper considers a finite-horizon setting and in each period, the distributor chooses its price and order quantity, while the manufacturer determines a wholesale price and its own replenishment quantity. The paper studies

the setting under decentralized decision making and proposes a price schedule that induces the distributor to adopt pricing and production strategies equal to those that would arise under centralized control. The paper by Granot and Yin [20] also studies a manufacturer selling a product to a retailer in a newsvendor setting with multiplicative, price-dependent demand. The manufacturer offers a contract to the retailer, and this firm determines the selling price and order quantity. The paper examines how the timing of the pricing and order-quantity decisions, with respect to the realization of random demand, affects the firms' profit performances. The paper by Ray *et al.* [21] studies a two-echelon system consisting of a distributor selling products through a retailer that faces stochastic price-sensitive demand. The retailer follows a continuous review base stock policy and faces a variable delivery lead time. The paper studies and compares optimal pricing and inventory decisions in a centralized setting and in a decentralized setting under a wholesale price contract.

Chen *et al.* [22] consider a two-echelon supply chain consisting of a supplier distributing a product through multiple noncompeting retail firms. Demand for each retailer occurs continuously at a constant rate, which decreases in the retailer's price. The retailers incur holding costs for the inventory they carry and fixed costs for the orders placed with the supplier. The supplier also incurs fixed and variable costs. The paper develops an efficient algorithm to determine the optimal pricing and replenishment strategy for the centralized system. The paper also considers a decentralized system in which the supplier and the retailers are independent profit-maximizing firms. In this setting, the supplier acts as the Stackelberg leader, offering the retailers a wholesale price that maximizes its profit, in anticipation of the subsequent joint pricing and replenishment strategy selected by the retailers. Chen *et al.* [23] identify a wholesale pricing mechanism that ensures that the retailers make their decisions in the decentralized system equal to those that would be made under centralized control.

Multiple Competing Retailers

Bernstein and Federgruen [24] consider a competing newsvendor setting in which multiple retail firms make pricing and order-quantity decisions. The distribution of a retailer's random demand depends on its own price as well as on those of the other retailers according to a general stochastic demand function. The paper analyzes the decentralized setting and provides conditions that ensure the existence of a unique price and order-quantity equilibrium. The paper then proceeds to the design of a coordinating contract arrangement that, if adopted, induces retailers to select the centralized optimal prices and order quantities. The paper by Zhao and Atkins [25] studies a setting with competitive newsvendors, in which firms compete simultaneously in terms of their prices and inventory levels. In their setting, a retailer's demand is a function of all firms' retail prices and stocking levels. Specifically, if demand at a particular retailer exceeds its available inventory, then a portion of the unsatisfied demand spills over to the retailer's competitors. The paper shows properties of each retailer's profit function that ensure the existence of a unique equilibrium.

In an infinite-horizon setting, Bernstein and Federgruen [26] study a two-echelon supply chain consisting of a supplier distributing a product through a network of competing retailers. In this setting, all firms incur inventory-carrying costs, while all supplier orders and transfers to the retailers incur fixed and variable costs. Like in Ref. 22, each retailer's demand occurs at a constant (deterministic) rate, over an infinite horizon. However, in this setting, a retailer's demand rate depends on the price charged by this retailer as well as those charged by its competitors. Alternatively, the price each retailer charges may depend on the sales volumes targeted by all the retailers, leading to quantity competition. The paper first characterizes the solution to the centralized system in which the joint pricing and replenishment decisions are determined to maximize chain-wide profit. This is followed by the analysis of the decentralized system, in which the

supplier acts as the Stackelberg leader offering a wholesale pricing scheme, followed by the retailers choosing their policy variables. The paper presents a condition that relates each retailer's price elasticity with the ratio of its annual sales to its combined inventory and fixed setup costs, that guarantees the existence of a unique Nash equilibrium. Finally, the paper proposes a wholesale pricing scheme that induces coordination.

In contrast to the deterministic demand setting explored in [26], Bernstein and Federgruen [27] explore a periodic review, infinite-horizon model in which in every period, each retailer faces a random demand volume. The distribution of a retailer's demand depends on all firms' retail prices. The paper considers the case of multiplicative demands and the more general case of nonmultiplicative demand structures, where the coefficient of variation of demand of each retailer may depend on its mean demand and, consequently, on all the prices in the market. The paper characterizes structural properties that guarantee the existence of an equilibrium of infinite-horizon joint pricing and replenishment strategies. It is shown that under retailer competition, and for the case of nonmultiplicative demand structures, a retailer's expected profit may decrease when reducing the uncertainty in its demand process.

Work on joint pricing and order quantity or production decisions also extends to assembly systems. In those settings, a number of firms (or suppliers) sell complementary products to a buyer (or assembler), who in turn, sells these items in a bundle (i.e., an assembled product). Wang [28] considers pricing and order-quantity decisions for a set of manufacturers that produce complementary products. Demand for the products (which are always purchased and consumed jointly) is random and occurs during a single selling season. The paper assumes a multiplicative demand model. The pricing and production decisions are made either simultaneously or sequentially. The paper characterizes and compares the firms' pricing and production equilibrium decisions and their resulting performance, under simultaneous and sequential decision making.

CONCLUSIONS

This article provides an overview of work addressing the joint determination of prices and inventory replenishment policies. The article reviews papers that focus on settings with a single firm and papers that consider more general settings with multiple firms. In settings with multiple firms, the article provides separate treatment for those papers that consider competition in the downstream market and those that assume that firms are geographically dispersed. Some of the papers reviewed in this article consider dynamic inventory and pricing decisions, while others restrict attention to static decisions. The case of dynamic joint pricing and replenishment decisions in settings with multiple competing firms represents a challenging but interesting direction for future research.

PRICING AND SCHEDULING DECISIONS

GAD ALLON
Kellogg School of Management,
Northwestern University,
Evanston, Illinois

Service providers as well as make-to-order manufacturers use priority schemes in conjunction with pricing as allocation mechanisms. By carefully selecting the appropriate scheduling scheme and the optimal prices, service providers can best utilize their resources to improve their customers' social welfare or improve their overall value (through improved service quality or cost reduction). This article studies the interplay between pricing and scheduling decisions focusing on the interaction between the service provider and the delay-sensitive customers, while dealing with different types of providers (a social planner, a monopolist, or oligopolies) in different types of service settings (either when the queues are observable or when they are not), and different types of customer populations (homogeneous or heterogeneous, segmented or unsegmented).

In exploring the relationship between pricing and scheduling decisions, we give separate treatment to different settings according to the role of service providers in the economy:

- *Social Planner.* In this case, the capacity of the service process is viewed as a scarce resource, and thus granting priorities is treated as such. The role of the pricing of the service is usually viewed in this context as a transfer mechanism to guarantee that only those who need high priority (due to high cost of delay or short service time) are granted this priority. In particular, pricing is used to ensure that the pricing-priority mechanism is incentive-compatible in the sense that customers have no incentive to misrepresent their true identity

when they hold such information privately (that is to claim that their delay cost is higher or service time is shorter). The pricing may also play a role in regulating usage in the system as a whole; this is a common practice in managing congested systems.

- *Monopolistic View.* In such a setting, the firm would like to use priorities and price them so as to improve its profits by virtue of price differentiation. When facing different types of customers, with different sensitivities to delay and different values obtained from the service, serving customers according to a priority rule while charging a priority-dependent price can outperform charging a fixed price, and serving according to a first-come-first-served manner. In settings in which there is asymmetric information regarding the identity of the customers, the prices and the priority schemes should be selected so that the overall pricing-priority mechanism is incentive-compatible.
- *Competitive View.* When competing in a market in which customers are sensitive to delay, firms can choose their prices, waiting time standards, capacity levels, and priority schemes. The role of the priority scheme is to allow the firm to accommodate all demand streams (driven by both the prices and the service level of the different segments), while meeting the promised service levels. As we will show, the price charged to each segment by each firm depends on the characteristics of all firms and also on the level of priority that the firm allocates to this specific segment.

We will initially review the use of priorities in models, where a social planner sets the prices and the scheduling rules. The main focus of these models will be on the incentive compatibility of the joint pricing-scheduling decisions. We will then survey settings where

profit-maximizing firms use the combination of pricing and scheduling, and which we will use to highlight the key differences between a social planner and a monopolist. We will initially discuss a setting in which the firm is not informed about the customer's waiting time cost and value, giving rise to incentive-compatible pricing and scheduling. We will also discuss the setting in which the queues are observable, giving rise to the phenomenon of "following the crowd" (which we will describe in detail). We will complete the article with a discussion of the role of priorities and pricing in the context of a competitive market. In this context, we will also discuss how pricing and scheduling decisions affect the benefits of each segment depending on the level of priority given to it. Note that the article deals with the interplay between pricing and scheduling in settings, which are modeled using queueing systems; that is, service settings and make-to-order manufacturers, and does not address make-to-stock settings.

These decisions have been considered (jointly) also in a make-to-stock environment. For examples of such models, see Charnsirisakskul *et al.* [1]. Also, for a more complete discussion of possible scheduling rules in queueing, see the article titled **Power Indices**. For a comprehensive discussion of strategic customer behavior in queueing, see the article titled **Strategic Customer Behavior in a Single Server Queue**. Lastly, for a discussion of the interplay between pricing and lead-time decisions, see the article titled **Pricing and Lead-Time Decisions**.

SOCIAL WELFARE MAXIMIZATION: INCENTIVE COMPATIBILITY

In many service systems, different customers typically have rather disparate sensitivities to the delay encountered, and obtain different value from the service. In order to improve the social welfare, a social planner can exploit these differences by optimally prioritizing among the different customers while charging them the optimal prices. The social planner, who maximizes the social welfare

of the players, views its limited available capacity as a scarce resource that needs to be allocated. Using the same logic, high priority is a scarce resource that needs to be properly allocated to those who need it. However, the design of optimal price and scheduling mechanisms may require knowledge of characteristics of the customers. These characteristics are seldom known to the queue manager and must be estimated or obtained from the customers' own statements, a situation that may create an incentive for customers to declare untruthful values.

The role of pricing, in many service systems, is to modulate demand. This is the case in particular for service providers striving to maximize social welfare, where customers are asked to pay for their use in order to make sure that the optimal usage level is achieved. Naor [2], for example, showed that in the context of homogeneous customers, tolls have to be levied in order to make sure that customers do not join the system when it is too congested. When customers are heterogeneous in terms of their waiting time cost and service times, the role of pricing is not only to regulate the usage in the different priority levels, (where, within each customer class, the optimal level of usage is achieved) but also to guarantee that customers either disclose their true costs or use the priority level that was designed to their needs and do not exploit the information asymmetry to obtain a higher priority than the one they deserve.

The question that this section tries to answer is how to construct a pricing mechanism that induces all customers to make decisions, which are not only optimal from their myopic, self-interested point of view, but also optimize the overall objective function of the organization.

Pricing Based on Externalities

Consider a model in which customers are identical except for having different costs of waiting, and priority levels are assigned to customers according to their declared costs. The information that is available to an arriving customer includes the queue length upon his arrival, the declared time values of the customers in the queue, and

the residual service time of the customer in service. Using this information, the customer declares a value to his time and obtains priority accordingly. The goal is to induce customers to declare their true time value, so that the resulting order of service optimizes social welfare. Dolan [3] suggested the use of Clarke prices. The idea is that each customer pays for the costs that he imposes on others when joining the queue. These costs are calculated given that customers reveal their true time value, which means that a customer pays an amount that is equal to the externalities that he imposes on other customers. It follows that under this pricing rule, the strategy that prescribes declaring the true time value is an equilibrium one. If a customer overstates his time cost, he must compensate the customers, who will have to wait longer as a result of this deviation by exactly the cost he saved (due to the work-conservation principle). Since these customers have higher waiting costs than his, compensating these customers for their increased waiting time costs the customer more than what he saves.

The model of Dolan [3] focuses on the ability to use a bidding rule, which is based on externalities, geared to induce customers to reveal their true delay cost. However, the model remains silent regarding the ability to use the pricing and the priority schemes to regulate usage and to control the arrival rate to the system, either to maximize profits or social welfare. Mendelson and Whang [4] address settings in which the arrival rate to the system is a function of the prices and the delay that the customers experience in the system.

Incentive Compatibility of the $c\mu$ Priority Rule

We now turn to the more general case, in which the service provider has to use pricing to regulate usage while being incentive-compatible. Consider a system that is modeled as an M/M/1 queueing system with multiple classes. Each class is characterized by its delay cost per unit of time and the expected service requirement. The goal is to find a pricing mechanism that is also optimal; that is, that the arrival rates and the scheduling scheme jointly maximize the

expected value of the system while allowing each customer to make individual decisions on whether or not to purchase the service and at what priority level. In making these decisions, while the customers are assumed to maximize their own utility functions under the optimal incentive-compatible pricing and scheduling schemes, they also maximize the objective of the organization as a whole.

When minimizing the expected organization-wide delay cost per unit of time, it is well known that given an exogenously specified arrival rate, and given that the delay cost and the expected service requirements are known, the optimal scheduling scheme is the so-called $c\mu$ rule, which gives absolute priority to customers according to the ratio of their delay cost to the expected service time required to complete their request. It is clear from the definition of the priority scheme that knowledge of these parameters is crucial for successful execution.

Mendelson and Whang [4] address the problem of resource pricing, which determines the demand rate of customers from each class, and priority pricing, which determines which customers are served at each point in time. For the case in which all customers have the same mean service times, regardless of their class, the authors show, in an analogous manner to Dolan [3], that charging each customer the externalities that he imposes on other customer classes under the optimal demand level, while using the $c\mu$ rule to prioritize among customers, is both optimal and incentive-compatible. In particular, the authors show that the optimal joint pricing-priority scheme automatically achieves incentive compatibility.

In the case of identical mean service times, the authors show that a price that depends only on the priority level is optimal and incentive-compatible. However, for the more general case, where customers differ in their delay cost as well as in their mean service time, such a pricing scheme may not be incentive-compatible anymore. In that case, the authors suggest a more general pricing scheme, which can be decomposed into two parts: a basic charge and a priority surcharge. The basic charge corresponds to the price of the lowest priority class, is equal

for all customers (regardless of their class or the priority they choose), and is quadratic in the service time. The priority charge is proportional to the service time with a coefficient that increases as the priority level goes up. One may view this pricing scheme as “externality pricing” in the following sense: when a customer buys a priority level, he pays the conditional expected externality of his decision on the other customers.

The main finding in this article is that the incentive-compatible pricing scheme induces the customers to behave in a way that is consistent with this rule, while aligning their interest with that of the overall organization. For a social planner, the prices are treated as transfer payments, whose objective is to merely be an instrument to regulate usage (both in the system as a whole and in each priority level). We next turn to ask how the pricing scheme and the scheduling decisions will change in a monopolistic setting.

PROFIT-MAXIMIZING PRICING AND SCHEDULING

Afeche [5] answers the question of how a capacity-constrained firm should design an incentive-compatible price-scheduling mechanism to maximize revenues from a heterogeneous pool of time-sensitive customers with private information on their willingness to pay, time-sensitivity, and processing requirements.

The article provides the following insights: First, the author shows that the familiar $c\mu$ rule, which is known to minimize the expected delay cost and to be incentive-compatible under social welfare optimization, need not be optimal in this setting. This specific fact suggests a more general guideline: in designing incentive-compatible and revenue-maximizing scheduling policies, delay cost-minimization, which plays a prominent role in controlling and pricing queueing systems, should not be a dominant criterion. Second, the author identifies optimal scheduling policies with novel features. One such policy prioritizes the more time-sensitive customers but voluntarily delays the completed orders of low

priority customers. This insertion of *strategic delays* deters time-sensitive customers from purchasing the lower-priority class. In other situations, the author shows that it is optimal to appropriately randomize priority assignment, in one extreme case, serving customers in reverse $c\mu$ order, which maximizes the system delay cost among all work-conserving policies. The author also shows that the optimal level of delay differentiation systematically emerges from a trade-off between operational constraints and customers’ incentives.

Numerical Example

In order to demonstrate the role of intentional delays, we will use a simple numerical example. Consider a firm that serves two types of customers:

1. H-type customers obtain \$100 from the service and incur \$20 per unit of time spent in the system.
2. L-type customers obtain \$30 from the service and incur \$4 per unit of time spent in the system.

We will assume that the arrival rates from each class is 0.2 H-type customers per unit of time, and 0.3 L-type customers per unit of time, independent of the price charged. We also assume that $\mu = 1$.

If the firm employs a $c\mu$ rule, the sojourn time of an H-type customer is $1/(1 - 0.2) = 1.25$. Using a similar logic, an L-type customer’s waiting time under the $c\mu$ rule is 2.5 time units.

If the firm tries to extract the entire consumer surplus, it would charge $\$75 = 100 - (1.25 \times 20)$ from each H-type customer, and $\$20 = 30 - (2.5 \times 4)$ from each L-type customer. This can presumably result in a revenue rate of $(0.2 \times 75) + (0.3 \times 20) = \21 per unit of time.

However, this solution is not incentive-compatible: Under this price and under this priority scheme, an H-type customer would opt to purchase the service grade designed for an L-type customer; this will leave him with utility of $100 - (2.5 \times 20) - 20 = 30$, which is better than what he obtains by purchasing

the service grade “designed” for him, which is $100 - (1.25 \times 20) = 75$.

Under the $c\mu$ rule, the highest incentive-compatible price that the firm can charge an H-type customer is \$45, which results approximately in a revenue rate of \$15 per unit of time. However, if the firm chooses to inject one unit of time of intentional delays for all L-type customers, the firm can charge only \$16 from each L-type customer, but the incentive-compatible price for the H-type customers is then \$61, which results in an increased revenue rate of $(3.2 \times 0.2) - (1.2 \times 0.3) > 0$. This means that the firm can improve its revenues by inserting artificial unnecessary delays. By degrading the quality of the low priority service, the service provider can charge more for high priority service. Note that in this case, the idleness is increasing the overall delay cost, yet the provider shrinks the pie in order to be able to “eat a larger piece.”

Bidding for Priorities in Observable Systems

We now turn to a discussion of the role of priority in systems in which the queue is observable to an arriving customer. We will first discuss several models that focus on the consumer behavior in such systems (fixing the priorities and the prices) and then discuss the behavior of a monopolist in such a market.

Consider an observable M/M/1 queue in which arriving customers choose from a discrete set of possible payments. In this model, customers are assigned priority levels according to their payments. All customers arriving to the system must obtain service (i.e., balking is not allowed), and customers are not informed on the payments made by others. Balachandran [6] shows that the equilibrium strategy of all customers is to choose the lowest price that will guarantee joining the head of the queue, which induces a “last-come-first-served” scheduling policy, when implemented by all customers. The rationale behind this equilibrium strategy is that a customer purchases high priority level not only because he can be scheduled ahead of other customers, but also so that others are not scheduled ahead of him. In many service systems, this leads to what Hassin and Haviv [7] refer to as “follow-the-crowd” behavior in which the

more customers purchase priority, the more inclined an individual is to do so himself. Haviv and Hassin [8] study a model with multiple priority classes in which agents can decide on joining strategies. While in a single class model, customers should follow a threshold policy; that is, join as long as the queue is below a certain level and balk otherwise. They showed that this is not true in a multiclass case.

The above models fix the pricing scheme and focus on the equilibrium behavior among customers in making the decision when to pay for priority, or how much to pay given the set of possible prices and priorities and in that, they are more descriptive of customer behavior in the presence of priorities.

The question that arises is how a monopolist utilizes such a consumer behavior when deciding what priority levels to offer the customers to choose from.

Alpersteins [9] considers a similar model in which the decisions on the available priorities and the associated prices are made by a profit-maximizing firm. Alperstein showed that the profit increases with the number of priority levels. The main conclusion from this model is that the profit-maximizing pricing scheme is one that induces a threshold of one for each priority type except for the highest one. That is, an arriving customer would always choose the lowest possible priority level that is above any existing customer.

COMPETITIVE MODELS

We will next discuss models in which service providers use prices in conjunction with priorities, to compete in the market. Examples of such industries are numerous. Banks and credit card companies segment their customers into regular and VIP or Gold and Platinum customers. Computer software and hardware firms often segment their customers, for example, into home and home office users, small businesses, large businesses and the government, education, and health-care sectors, using an integrated pool of technical support personnel to serve the different customer segments according to a specific priority discipline; each customer

segment is associated with a specific price and waiting time expectation. Finally, overnight delivery services use their planes and trucks to deliver letters, boxes, and cargo, each with different prices and delivery time standards. In many service industries, waiting time standards are used as a primary advertised competitive instrument. For example, most major electronic brokerage firms, (e.g., Ameritrade, Fidelity, and E-trade) all prominently feature the average or median execution speed per transaction, which is monitored by independent firms.

References Loch [10], Lederer and Li [11], and Armony and Haviv [12] as well as Allon and Federgruen [13] are the only published articles we are aware of that have directly addressed competition models in which waiting-time-sensitive customers are segmented into multiple classes. We will briefly survey the first three and then discuss in greater detail the model presented in Allon and Federgruen [13].

Loch [10] considers an industry with M/M/1 service providers and two customer classes, each with a given waiting cost rate and average service time. All customers within a class select the firm, which offers the lowest full price; that is, the sum of the direct price and the waiting cost, where the total demand volume in the class is given by a known function of this full price value. Under quantity competition, the author establishes the existence of a Nash equilibrium under which the customers are prioritized according to the $c\mu$ rule. Lederer and Li [11] generalize this model to allow for an arbitrary number of nonidentical M/G/1 firms and an arbitrary number of customer classes. Assuming the firms engage in price competition, the authors establish the existence of a Nash equilibrium, under which each firm, once again, prioritizes customers according to the $c\mu$ rule. The existence result is based on the assumption that each class' expected waiting time at a given firm is a convex function of all of the firm's demand rates for the different customer classes. Note also that while in Afeche's [5] monopoly model, the incentive-compatible optimal policy cannot, in general, be based on the $c\mu$ priority rule; the $c\mu$ priority rules are part of

the Nash equilibrium in Lederer and Li's [11] perfect price competition model (provided the above convexity assumption is satisfied).

Armony and Haviv [12] analyze a two-stage competition model with two M/M/1 service providers and two customer classes, each, again, acting as a single entity in deciding what fraction of its business to assign to each of the providers. In the first stage, the two providers compete with each other by announcing their service charges. In the second stage, the customer classes compete with their allocation decisions. They show that pure price equilibrium may fail to exist in this two-stage game.

All of the previous models assume that the service organization (or the make-to-order manufacturer) has a fixed capacity and thus the role of the priority rule is to allocate the capacity among the different customers according to their cost of waiting as well as their expected service requirements.

We next present a more general model in which the firm can invest in capacity in order to accommodate the different customers, in conjunction with a priority rule, in a way that will allow the firm to position itself in the market. In such markets, firms cater to multiple customer classes or market segments with the help of shared service facilities or processes, so as to exploit pooling benefits. As in all of the settings studied in the previous section, different customer classes typically have rather disparate sensitivities to the price of service as well as the delays encountered. Thus, from the firm's perspective, it is vital to offer differentiated service charges and levels of service to different customer classes so as to maximize (long run) profits.

Allon and Federgruen [13] propose and analyze a model in which firms select all or part of the following: (i) the prices charged to all customer classes, (ii) the waiting time standards promised to all classes measured in terms of the average waiting time, (iii) the capacity level, and (iv) a priority discipline enabling the firm to meet the promised waiting time standards under the chosen capacity level. While making these decisions in a competitive setting can be quite complex, one can observe that while the price and the waiting time decisions impact all firms in the

industry, the capacity and the priority (given the demand and the waiting time standard) impact only the cost of the firm itself. The authors, thus, first present the capacity problem, in conjunction with the priority setting. The authors then embed them in the competitive setting in which firms compete in terms of their prices.

Capacity Choice and Associated Priority Rules

Consider a service provider, modeled as an M/M/1 queueing facility. Each customer class generates an independent Poisson stream of customers to this service provider at the rate determined by the above-mentioned demand functions. Its service times are i.i.d. with a firm- and class-dependent service rate that is proportional to the firm's capacity level. Each firm incurs a given class-dependent cost per customer, as well as a cost per unit of time, proportional to the adopted capacity level. Each firm attempts to maximize its expected profits.

Allon and Federgruen [13] derive the analytical expression of the capacity level that each firm needs to adopt to accommodate a given vector of demand volumes and waiting time standards under an optimal associated dynamic priority rule. They show that this capacity level is the maximum of a number of closed-form capacity bounds, one for each subset of the customer classes. Interestingly, for arbitrarily specified waiting time standards, the maximum may be achieved for a strict subset of the collection of all classes, the so-called *bottleneck set*, in which case strategic idleness times, that is artificial after-service delays, may be adopted for the so-called *residual* classes outside the bottleneck set. The optimal capacity level is to be complemented with a randomized absolute priority rule.

The authors study three types of competition: price competition (where waiting times are exogenously determined), waiting time competition (when the prices are exogenously determined), and simultaneous price-waiting time competition. They show that in the waiting time and the simultaneous competition models, the bottleneck set is always the full set. However, this is not necessarily true in the price competition model, where

waiting times are not part of the strategic choices. Thus the need for intentional delays may arise only under price competition.

It is important to note that we again see the use of intentional delays, when selecting capacity levels and priority schemes as observed already, in a different setting and for a different purpose in Afèche [14].

Pooled versus Dedicated Capacity

The authors then compare the equilibria that arise when the firms use pooled capacity with those achieved when the firms service each market segment with a dedicated service process; that is, without pooling service resources. In the price competition model, for example, the equilibrium is obtained, both under service pooling and dedicated service facilities, when for each class the relative markup vis-a-vis the marginal cost equals the reciprocal of the demand elasticity. The marginal cost per customer per unit of time always consists of the variable service cost plus the marginal capacity cost (per unit of time). When service is provided with dedicated facilities, the marginal increase in the required capacity equals the expected amount of work per customer of the considered class. Under service pooling, it is zero for residual classes and less (or more) than this benchmark value, depending upon whether the customer class receives worse (or better) than average service.

Allon and Federgruen [13] then show that, while all firms reduce their total cost by switching from dedicated to pooled service, these cost savings do not necessarily result in price reductions for all customer classes. Indeed, if a customer class gets better than average service (and belongs to the bottleneck set) at all firms, it is charged a higher price under service pooling than under dedicated service. The following provides some intuition behind this result: assume all classes initially get identical normalized waiting time standards; if class 1, say, subsequently bargains for a lower waiting time standard, the cost for the other customer classes increases,

for which externalities class 1 is made to pay.

CONCLUSIONS

Many service providers use pricing and scheduling schemes in order to improve their value proposition. In summarizing this article, it is important to highlight several important concepts that arise in the intersection between pricing and scheduling.

1. *Externalities-Based Pricing.* The concept of charging customers the externalities that they impose on other customers arises in settings in which the customers have private information regarding their delay cost as well as in settings in which firms compete while investing in a pooled capacity to accommodate different segments. The former is used to achieve incentive compatibility while the latter to make sure that different segments, those with high service levels as well as those with low service levels, are charged a competitive price.
2. *Intentional Delays.* While in many cases service organizations set priorities to minimize the total waiting time cost, via the $c\mu$ rule, this is not always the case. Both, when a monopolist needs to set priorities that are incentive-compatible and profit-maximizing, as well as in the case in which the firm needs to choose its capacity level in conjunction with priority rules in order to accommodate different service levels, the firm might be introducing intentional delays. The idea is to delay the customers of one of the segments upon completion to achieve different goals that cannot be achieved when restricted to waiting-time-minimizing rules.
3. *Follow-the-Crowd Behaviour.* The consumer behavior in the simplest service system, the M/M/1 queue, can be characterized as “avoid-the-crowd” behaviour: customers prefer joining the queue when others do not do so.

However, in the presence of priorities, the consumer behavior can be characterized as “follow-the-crowd” behaviour: the more customers purchase priorities, the more likely other customers purchase these as well. As discussed above, a monopolist can exploit such behavior when introducing pricing and scheduling scheme to customers.

HISTORICAL NOTE

In 1797 in his book “Theorie des fonctions analytiques” Joseph Luis Lagrange (1736–1813) introduced the Lagrangian and Lagrange multipliers rule for solving optimization problems with equality constraints.

... If a function of several variables should be a maximum or minimum and there are between these variables one or several equations, then it will be suffice to add to the proposed function the functions that should be zero, each multiplied by an undetermined quantity, and then to look for the maximum and the minimum as if the variables were independent; the equation that one will find combined with the given equations, will serve to determine all the unknowns.

J.-L. Lagrange

The Lagrange multipliers rule is only a necessary but not sufficient condition for an equality constrained optimum. The primal–dual (PD) vector is neither a maximum nor a minimum of the Lagrangian: it is a saddle point. Nevertheless, for more than 200 years the Lagrangian has remained an invaluable tool for optimization. Moreover, with time, the great value of the Lagrangian has become increasingly evident. The Lagrangian is the main instrument for establishing optimality conditions, the basic

ingredient in the Lagrange duality, and one of the most important tools in numerical constrained optimization. Any PD method for solving constrained optimization problems in one way or another uses the Lagrangian and the Lagrange multipliers.

OPTIMIZATION WITH EQUALITY CONSTRAINTS: LAGRANGE SYSTEM OF EQUATIONS

Consider $q + 1$ smooth enough functions $f, g_j : \mathbb{R}^n \rightarrow \mathbb{R}$, $j = 1, \dots, q$ and the feasible set

$$\Omega = \{x : g_j(x) = 0, j = 1, \dots, q\}.$$

The equality constrained optimization (ECO) problem consists of finding

$$(\mathcal{ECO}) \quad f(x^*) = \min\{f(x) | x \in \Omega\}.$$

The Lagrangian $L : \mathbb{R}^n \times \mathbb{R}^q \rightarrow \mathbb{R}^1$ for (ECO) is given by the formula

$$L(x, v) = f(x) - \sum_{j=1}^q v_j g_j(x).$$

Let us consider the vector function $g^T(x) = (g_1(x), \dots, g_q(x))$, the Jacobian $J(g(x)) = \nabla g(x) = (\nabla g_1(x), \dots, \nabla g_q(x))^T$ and assume

$$\text{rank } \nabla g(x^*) = q < n. \quad (1)$$

Then for x^* to be a (ECO) solution, it is necessary the existence of $v^* \in \mathbb{R}^q$ that the pair (x^*, v^*) is a solution to the following Lagrange system of equations:

$$\nabla_x L(x, v) = \nabla f(x) - \nabla g^T(x)v = 0, \quad (2)$$

$$g_i(x) = 0, \quad i = 1, \dots, q. \quad (3)$$

We consider the Hessian

$$\nabla_{xx}^2 L(x, v) = \nabla^2 f(x) - \sum_{i=1}^q v_i \nabla^2 g_i(x)$$

of the Lagrangian $L(x, v)$. The regularity condition (1), together with sufficient condition for the minimizer x^* to be isolated that is

$$\begin{aligned} \langle \nabla_{xx}^2 L(x^*, v^*) \xi, \xi \rangle &\geq m \langle \xi, \xi \rangle, \\ \forall \xi : \nabla g(x^*) \\ \xi &= 0, m > 0, \end{aligned} \quad (4)$$

comprise the standard second-order optimality conditions for the $(\mathcal{ECO})$ problem.

Application of Newton's method to the nonlinear PD system of Equations (2), (3) leads to one of the first PD methods for constrained optimization [1].

By linearizing the system (2), (3) and ignoring terms of the second and higher order, one obtains the following linear PD system for finding the Newton direction $(\Delta x, \Delta v)$:

$$\begin{bmatrix} \nabla_{xx}^2 L(\cdot) & -\nabla g^T(\cdot) \\ \nabla g(\cdot) & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta v \end{bmatrix} = \begin{bmatrix} -\nabla_x L(\cdot) \\ -g(\cdot) \end{bmatrix}. \quad (5)$$

PDECOM-Primal-Dual Equality Constrained Optimization Method

Step 0. Let $y \in S(y^*, \delta)$.

Step 1. If $v(y) \leq \epsilon$, Output y as the solution.

Step 2. Find Δx and Δv from (5).

Step 3. Update the primal-dual pair by the following formulas

$$x := x + \Delta x, \quad v := v + \Delta v.$$

Step 4. Goto Step 1.

If the standard second-order optimality conditions for $(\mathcal{ECO})$ are satisfied, the Lipschitz conditions for the Hessians $\nabla^2 f(x)$, $\nabla^2 g_i$, $i = 1, \dots, q$ hold, $y = (x, v) \in S(y^*, \delta)$ and $\delta > 0$ is small enough, then the PDECOM generates the PD sequence that converges to the PD solution $y^* = (x^*, v^*)$ with quadratic rate; that is, the following bound holds:

$$\|\hat{y} - y^*\| \leq C \|y - y^*\|^2, \quad (9)$$

where $C > 0$ is independent from $y \in S(y^*, \delta)$ and depends only on the problem data [1].

Let $S(y^*, \delta) = \{y = (x, v) : \|y - y^*\| \leq \delta\}$, where $\|\cdot\|$ is the Euclidean norm, δ small enough, and $0 < \epsilon \ll \delta$ is the desired accuracy. The following merit function

$$\begin{aligned} v(y) &= v(x, v) \\ &= \max \left\{ \|\nabla_x L(x, v)\|, \max_{1 \leq i \leq q} |g_i(x)| \right\}, \end{aligned} \quad (6)$$

measures the distance between the PD approximation (x, v) and the solution (x^*, v^*) . If f and g_i are smooth enough and the second-order optimality conditions for $(\mathcal{ECO})$ are satisfied, then for $y \in S(y^*, \delta)$ we have

$$v(y) = 0 \Leftrightarrow y = y^*, \quad (7)$$

and there are $0 < m_0 < M_0$ that

$$m_0 \|y - y^*\| \leq v(y) \leq M_0 \|y - y^*\|. \quad (8)$$

The PD method for $(\mathcal{ECO})$ consists of the following operations:

AUGMENTED LAGRANGIAN AND PRIMAL-DUAL AUGMENTED LAGRANGIAN METHOD

For a given $k > 0$, the augmented Lagrangian (AL) $\mathcal{L} : \mathbb{R}^n \times \mathbb{R}^q \times \mathbb{R}_+ \rightarrow \mathbb{R}^1$ is defined by the following formula [2,3]:

$$\mathcal{L}(x, v, k) = f(x) - \sum_{j=1}^q v_j g_j(x) + \frac{k}{2} \sum_{j=1}^q g_j^2(x). \quad (10)$$

The AL method alternates the unconstrained minimization of the AL $\mathcal{L}(x, v, k)$ in the primal space with a Lagrange multipliers update.

Let $\delta > 0$ be sufficiently small, $0 < \epsilon \ll \delta$ be the desired accuracy, $k > 0$ be sufficiently large, and $y = (x, v) \in S(y^*, \delta)$. One step of the classical AL method consists of finding the primal minimizer

$$\hat{x} = \arg \min_{x \in \mathbb{R}^n} \mathcal{L}(x, v, k), \quad (11)$$

followed by the Lagrange multipliers update.

In other words, for a given scaling parameter $k > 0$ and a starting point $y = (x, v) \in S(y^*, \delta)$, one step of the AL method is equivalent to solving the following nonlinear PD system for $\hat{x}$ and $\hat{v}$:

$$\nabla_x L(\hat{x}, \hat{v}) = \nabla f(\hat{x}) - \sum_{j=1}^q \hat{v}_j \nabla g_j(\hat{x}) = 0, \quad (12)$$

$$\hat{v} - v + kg(\hat{x}) = 0. \quad (13)$$

PDALM - Primal-Dual Augmented Lagrangian Method

Step 0. Let $y \in S(y^*, \delta)$ and $k > 0$ is large enough.

Step 1. If $v(y) \leq \epsilon$, Output y as a solution.

Step 2. Set $k = v(x, v)^{-1}$.

Step 3. Find Δx and Δv from (14).

Step 4. Update the primal-dual pair by the formulas

$$x := x + \Delta x, \quad v := v + \Delta v.$$

Step 5. Goto Step 1.

If the standard second-order optimality conditions for $(\mathcal{ECO})$ are satisfied, the Lipschitz conditions for the Hessians $\nabla^2 f(x)$, $\nabla^2 g_i$, $i = 1, \dots, q$ hold, $y = (x, v) \in S(y^*, \delta)$, and $\delta > 0$ is sufficiently small, then the PDALM generates a PD sequence that converges to the PD solution $y^* = (x^*, v^*)$ with a quadratic rate, that is Equation (9) holds [4].

OPTIMIZATION WITH INEQUALITY CONSTRAINTS

Let $f: \mathbb{R}^n \rightarrow \mathbb{R}^1$ be convex and all $c_i: \mathbb{R}^n \rightarrow \mathbb{R}^1$, $i = 1, \dots, p$ be concave and

Application of Newton's method for solving the PD system (12)–(13) for $(\hat{x}, \hat{v})$ together with a proper update of the penalty parameter $k > 0$ leads to the primal-dual augmented Lagrangian (PDAL) method for solving $(\mathcal{ECO})$ problems [4].

By linearizing the system (12)–(13) and ignoring terms of the second and higher order, we obtain the following linear PD system for finding the Newton direction $(\Delta x, \Delta v)$:

$$\begin{bmatrix} \nabla_{xx}^2 L(\cdot) & -\nabla g^T(\cdot) \\ \nabla g(\cdot) & \frac{1}{k} I_q \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta v \end{bmatrix} = \begin{bmatrix} -\nabla_x L(\cdot) \\ -g(\cdot) \end{bmatrix}, \quad (14)$$

where I_q is the identity matrices in $\mathbb{R}^q$. Note that if $k \rightarrow \infty$, then the system (14) gets close to the system (5). Therefore, by changing $k > 0$ properly it is possible to achieve a quadratic rate of convergence for the PDAL method.

smooth functions. Consider a convex set $\Omega = \{x \in \mathbb{R}^n : c_i(x) \geq 0, i = 1, \dots, p\}$ and the following convex inequality constrained optimization (ICO) problem:

$$(\mathcal{ICO}) \quad f(x^*) = \min\{f(x) | x \in \Omega\}.$$

Let us assume that

- (a) The primal optimal set X^* is not empty and bounded.
- (b) The Slater's condition holds; that is, there exists $\hat{x} \in \mathbb{R}^n : c_i(\hat{x}) > 0, i = 1, \dots, p$.

Due to the assumption **B**, the Karush–Kuhn–Tucker’s (KKT’s) conditions hold true; that is, there exists a vector $u^* = (u_1^*, \dots, u_p^*) \in \mathbb{R}_+^p$ such that

$$\nabla_x L(x^*, u^*) = \nabla f(x^*) - \sum_{i=1}^p u_i^* \nabla c_i(x^*) = 0, \quad (15)$$

$$c_i(x^*) \geq 0, \quad u_i^* \geq 0, \quad i = 1, \dots, p, \quad (16)$$

and the complementary slackness conditions

$$u_i^* c_i(x^*) = 0, \quad i = 1, \dots, p \quad (17)$$

hold true.

Let $I = \{i : c_i(x^*) = 0\} = \{1, \dots, r\}$ be the set of indices of the active at x^* constraints, $c_{(r)}^T(x) = (c_1(x), \dots, c_r(x))$ be the vector function of the active at x^* constraints and $\nabla c_{(r)}(x) = J(c_{(r)}(x))$ be the corresponding Jacobian. The standard second-order optimality conditions for (ICO) consists of existence $u^* \in \mathbb{R}_+^p$ and $m > 0$ such that

$$\text{rank}(\nabla c_{(r)}(x^*)) = r, \quad u_i^* > 0, \quad i = 1, \dots, r \quad (18)$$

and

$$\langle \nabla_{xx}^2 L(x^*, u^*) \xi, \xi \rangle \geq m \langle \xi, \xi \rangle, \quad \forall \xi : \nabla c_{(r)}(x^*) \xi = 0. \quad (19)$$

The dual to (ICO) problem consists of finding

$$(\mathcal{D}) \quad d(u^*) = \max \{d(u) | u \in \mathbb{R}_+^p\},$$

where $d(u) = \inf_{x \in \mathbb{R}^n} L(x, u)$ is the dual function.

For convex (ICO) that satisfies the Slater condition we have

$$f(x^*) = d(u^*).$$

The PD methods generate PD sequences $\{x^s, u^s\}_{s=1}^\infty$ that

$$f(x^*) = \lim_{s \rightarrow \infty} f(x^s) = \lim_{s \rightarrow \infty} d(u^s) = d(u^*).$$

LOG-BARRIER FUNCTION AND INTERIOR-POINT METHODS

The (ECO) problem is not combinatorial by nature because all constraints are active at the solution (by definition, active constraints are those that are satisfied as equalities). At the same time, the methods for (ECO) require an initial approximation from the neighborhood $S(y^*, \delta)$. The (ICO) in general and convex (ICO) in particular, are combinatorial by nature because the set of active at the solution constraints is unknown *a priori*. On the other hand, for convex (ICO) there is no need to have an initial approximation $y \in S(y^*, \delta)$.

Consider PD interior-point methods for convex optimization that are based on the classical log-barrier function $\beta : \text{int } \Omega \times \mathbb{R}_+ \rightarrow \mathbb{R}$ defined by the formula

$$\beta(x, \mu) = f(x) - \mu \sum_{i=1}^p \ln c_i(x).$$

Let $\ln t = -\infty$ for $t \leq 0$; then for any given $\mu > 0$ the Frisch log-barrier function $F : \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}$ is defined as follows:

$$F(x, \mu) = \begin{cases} \beta(x, \mu), & x \in \text{int } \Omega; \\ \infty, & x \notin \text{int } \Omega. \end{cases}$$

The classical sequential unconstrained minimization technique (SUMT) [5] finds the PD trajectory $\{y(\mu) = (x(\mu), u(\mu))\}$ by the following formulas:

$$\begin{aligned} \nabla_x F(x(\mu), \mu) &= \nabla f(x(\mu)) \\ - \sum_{i=1}^p \mu (c_i(x(\mu)))^{-1} \nabla c_i(x(\mu)) &= 0 \end{aligned} \quad (20)$$

and

$$\begin{aligned} u(\mu) &= (u_i(\mu)) = \mu (c_i(x(\mu)))^{-1}, \\ i &= 1, \dots, p. \end{aligned} \quad (21)$$

Equation (20) is the optimality condition for the unconstrained problem

$$x(\mu) = \arg \min \{F(x, \mu) | x \in \mathbb{R}^n\}.$$

Thus, for a given $\mu > 0$, finding the PD approximation from Equations (20), (21) is equivalent to solving the following system for $(\hat{x}, \hat{u})$:

$$\begin{aligned} \nabla_x L(\hat{x}, \hat{u}) &= \nabla f(\hat{x}) - \sum_{i=1}^p \hat{u}_i \nabla c_i(\hat{x}) = 0, \\ \hat{u}_i c_i(\hat{x}) &= \mu, \quad i = 1, \dots, p. \end{aligned} \quad (22)$$

It follows from Equation (20) that $x(\mu) \in \text{int } \Omega$. It follows from Equation (21) that $u(\mu) \in \mathbb{R}_{++}^p$, that is $x(\mu)$ and $u(\mu)$ are primal and dual interior points. It follows from Equations (20), (21) that

$$\nabla_x F(x(\mu), \mu) = \nabla_x L(x(\mu), u(\mu)) = 0,$$

or

$$d(u(\mu)) = \min_{x \in \mathbb{R}^n} L(x, u(\mu)) = L(x(\mu), u(\mu))$$

and the PD gap (i.e., the difference between the values of the primal and dual objective functions) is

$$\begin{aligned} \Delta(\mu) &= f(x(\mu)) - d(u(\mu)) \\ &= \sum_{i=1}^p u_i(\mu) c_i(x(\mu)) = p\mu, \end{aligned}$$

that is

$$\lim_{\mu \rightarrow 0} x(\mu) = x^* \quad \text{and} \quad \lim_{\mu \rightarrow 0} u(\mu) = u^*. \quad (23)$$

Finding $(\hat{x}, \hat{u}) = (x(\mu), u(\mu))$ or its approximation from Equation (22) and reducing $\mu > 0$ is the main idea of the SUMT [5].

Solving the nonlinear PD system (22) is an infinite procedure in general. The main idea of the PD interior-point methods is to replace the nonlinear PD system (22) by one Newton step toward solution of the system (22) and follow that by the barrier parameter update. For a given approximation $y = (x, u)$ and the barrier parameter $\mu > 0$, the application of Newton's method to the nonlinear PD system

(22) leads to the following linear PD system:

$$\begin{bmatrix} \nabla_{xx}^2 L(x, u) & -\nabla c(x)^T \\ U \nabla c(x) & C(x) \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta u \end{bmatrix} = \begin{bmatrix} -\nabla L(x, u) \\ -U c(x) + \mu e \end{bmatrix}, \quad (24)$$

where $C(x) = \text{diag } (c_i(x))_{i=1}^p$, $U = \text{diag } (u_i)_{i=1}^p$, and $e = (1, \dots, 1)^T \in \mathbb{R}^p$.

The system (24) finds the Newton direction $\Delta y = (\Delta x, \Delta u)$, which is used to update the current approximation $y = (x, u)$:

$$\bar{x} = x + \alpha \Delta x; \quad \bar{u} = u + \alpha \Delta u. \quad (25)$$

One must determine the step length $\alpha > 0$ in such a way that a new approximation $\bar{y} = (\bar{x}, \bar{u})$ not only remains primal and dual interior, but also remains in the area for which Newton's method for PD system (22) is well defined for the updated barrier parameter [6]. For some classes of constrained optimization problems, including linear programming problems (LPs) and quadratic programming problems (QPs), it is possible to take $\alpha = 1$ in Equation (25) and update the barrier parameter μ by the formula $\bar{\mu} = \mu(1 - \rho/\sqrt{n})$, where $0 < \rho < 1$ is independent on n . The new approximation belongs to the neighborhood of the solution of the system (22) with μ replaced by $\bar{\mu}$. Moreover, each step reduces the PD gap by the same factor $(1 - \rho/\sqrt{n})$. This leads to polynomial complexity of the PD interior-point methods for LP and QP [6]. LP, QP, and QP with quadratic constraints problems are well structured, which means that constraints and epigraph of the objective function can be equipped with a self-concordant (SC) barrier [7,8].

If (ICQ) problem is not well structured, establishing polynomial complexity of the path-following methods becomes problematic, if not impossible. Nevertheless, the PD interior-point approach remains productive and leads to globally convergent and numerically efficient PD methods [9–13].

There are two main classes of PD methods for (ICQ): interior-point PD method based on the path-following idea (which goes back to SUMT) and exterior-point PD methods (which are based on nonlinear rescaling (NR) theory [14–16]).

PRIMAL-DUAL INTERIOR-POINT METHODS

corresponds to (ECO) (27).

Consider the following problem

$$\begin{aligned} \min & f(x), \\ \text{s.t. } & c(x) - w = 0, \\ & w \geq 0, \end{aligned} \quad (26)$$

which is equivalent to (ICO) problem.

The log-barrier function $F(x, w, \mu) = f(x) - \mu \sum_{i=1}^p \ln w_i$ is used to handle the nonnegativity of the slack vector $w \in \mathbb{R}_+^p$, which guarantees the primal feasibility.

One step of the path-following method consists of solving the following (ECO) problem:

$$\begin{aligned} \min & F(x, w, \mu), \\ \text{s.t. } & c(x) - w = 0, \end{aligned} \quad (27)$$

followed by the barrier parameter $\mu > 0$ update.

The Lagrangian for the problem (27) is defined by formula

$$\begin{aligned} L(x, w, u) \\ = f(x) - \mu \sum_{i=1}^p \log w_i - \sum_{i=1}^p u_i (c_i(x) - w_i). \end{aligned}$$

Let $W = \text{diag}(w_i)_{i=1}^p$ and $U = \text{diag}(u_i)_{i=1}^p$. The following Lagrange system of equations

$$\begin{aligned} \nabla f(x) - \nabla c(x)^T u &= 0 \\ -\mu e + W U e &= 0 \\ c(x) - w &= 0 \end{aligned} \quad (28)$$

Application of Newton's method to nonlinear PD system (28) leads to the following linear PD system for finding the Newton directions:

$$\begin{bmatrix} \nabla_{xx}^2 L(x, u) & 0 & -\nabla c(x)^T \\ 0 & U & W \\ \nabla c(x) & -I_p & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta w \\ \Delta u \end{bmatrix} = \begin{bmatrix} -\nabla f(x) + \nabla c(x)^T u \\ \mu e - W U e \\ -c(x) + w \end{bmatrix}, \quad (29)$$

where $\nabla_{xx}^2 L(x, u) = \nabla^2 f(x) - \sum_{i=1}^p u_i \nabla^2 c_i(x)$ is the Hessian in x of the Lagrangian for (ICO) problem.

For convex (ICO) the merit function

$$\begin{aligned} v(y) \equiv v(x, w, u) &= \max \{ \|\nabla_x L(x, w, u)\|, \\ &\quad \|c(x) - w\|, \|W U e\|, \} \end{aligned}$$

is used. Under the standard second-order optimality conditions, the merit function $v(y)$ satisfies Equations (7) and (8).

Take $\delta > 0$ to be sufficiently small and $0 < \epsilon \ll \delta$ to be the defined accuracy. Consider the following PD interior-point method:

PDIPM - Primal-Dual Interior-Point Method

Step 0. Let $y \in S(y^*, \delta) = \{y : \|y - y^*\| \leq \delta\}$ be the initial approximation.

Step 1. If $v(x, w, u) \leq \epsilon$, Output $y = (x, u)$ as a solution.

Step 2. Calculate the barrier parameter $\mu = \min \{\theta \mu, v^2(x, w, u)\}$, $0 < \theta < 1$.

Step 3. Find Δx , Δw , and Δu from (29).

Step 4. Calculate the parameter κ and the step lengths α_P and α_D by formulas

$$\begin{aligned} \kappa &= \max \{ \bar{\kappa}, 1 - v(x, w, u) \}, \quad 0 < \bar{\kappa} < 1, \\ \alpha_P &= \min_{1 \leq i \leq m} \left\{ 1; -\kappa \frac{(w^s)_i}{(\Delta w^s)_i} : (\Delta w^s)_i < 0 \right\}, \\ \alpha_D &= \min_{1 \leq i \leq m} \left\{ 1; -\kappa \frac{(u^s)_i}{(\Delta u^s)_i} : (\Delta u^s)_i < 0 \right\}. \end{aligned}$$

Step 5. Update the primal-dual pair by the formulas

$$\hat{x} := x + \alpha_P \Delta x, \quad \hat{w} := w + \alpha_P \Delta w, \quad \hat{u} := u + \alpha_D \Delta u.$$

Step 6. Goto Step 1.

If the standard second-order optimality conditions are satisfied for $(\mathcal{ICO})$, the Hessians $\nabla^2 f(x)$ and $\nabla^2 c_i(x)$, $i = 1, \dots, p$ are Lipschitz continuous, $\delta > 0$ is sufficiently small, and a starting point $y \in S(y^*, \delta)$, then the PD sequence generated by the PDIPM converges to the KKT's point with a quadratic rate [10,17].

PRIMAL-DUAL NONLINEAR RESCALING METHOD

Consider a class Ψ of strictly concave and twice continuously differentiable functions $\psi : (t_0, t_1) \rightarrow \mathbb{R}$, $-\infty < t_0 < 0 < t_1 < \infty$ that satisfy the following properties:

- 1⁰. $\psi(0) = 0$.
- 2⁰. $\psi'(t) > 0$.
- 3⁰. $\psi'(0) = 1$.
- 4⁰. $\psi''(t) < 0$.
- 5⁰. there is $a > 0$ that $\psi(t) \leq -at^2$, $t \leq 0$.
- 6⁰. $a)\psi'(t) \leq b_1 t^{-1}$, $b) -\psi''(t) \leq b_2 t^{-2}$, $t > 0$,
 $b_1 > 0, b_2 > 0$.

The following transformations $\psi \in \Psi$ satisfy the above properties:

1. Exponential transformation [18]

$$\psi_1(t) = 1 - e^{-t}.$$

2. Logarithmic MBF [14]

$$\psi_2(t) = \ln(t + 1).$$

3. Hyperbolic MBF [14]

$$\psi_3(t) = \frac{t}{1+t}.$$

Each of the above transformations can be modified in the following way. For a

given $-1 < \tau < 0$ we define quadratic extrapolation of the transformations 1 – 3 by the formulas

4.

$$\psi_{q_i}(t) = \begin{cases} \psi_i(t), & t \geq \tau, \\ q_i(t) = a_i t^2 + b_i t + c_i, & t \leq \tau, \end{cases}$$

where a_i, b_i, c_i one finds from the following equations: $\psi_i(\tau) = q_i(\tau)$, $\psi'_i(\tau) = q'_i(\tau)$, $\psi''_i(\tau) = q''_i(\tau)$.

Modification 4 leads to transformations that are defined on $(-\infty, \infty)$ and, along with penalty function properties, have some additional important features [15,16,19].

Due to 1⁰ – 3⁰ for any $\psi \in \Psi$ and any $k > 0$, the following problem

$$f(x^*) = \min \left\{ f(x) | k^{-1} \psi(k c_i(x)) \geq 0, \right. \\ \left. i = 1, \dots, p \right\} \quad (30)$$

is equivalent to the original $(\mathcal{ICO})$ problem. The classical Lagrangian $\mathcal{L} : \mathbb{R}^n \times \mathbb{R}_+^p \times \mathbb{R}_+ \rightarrow \mathbb{R}^1$ for the equivalent problem (30) is defined by the formula

$$\mathcal{L}(x, u, k) = f(x) - k^{-1} \sum_{i=1}^p u_i \psi(k c_i(x)).$$

The NR principle consists of transforming the original $(\mathcal{ICO})$ problem into an equivalent one and then using the classical Lagrangian for the equivalent problem for theoretical analysis and numerical methods. In contrast to SUMT, the NR principle leads to exterior-point methods. Convergence of the NR methods is due to both, the Lagrange multipliers and the scaling parameter updates.

We use the following merit function:

$$v \equiv v(x, u) = \max \left\{ \|\nabla_x L(x, u)\|, -\min_{1 \leq i \leq p} c_i(x), \sum_{i=1}^p |u_i| |c_i(x)|, -\min_{1 \leq i \leq p} u_i \right\}. \quad (31)$$

For convex (ICCO) under the standard second-order optimality condition, the merit function (31) satisfies Equations (7) and (8).

For a given $u \in \mathbb{R}_{++}^p$ and $k > 0$, one step of the NR method with scaling parameter update consists in finding

$$\hat{x} = \arg \min \{ \mathcal{L}(x, u, k) \mid x \in \mathbb{R}^n \}, \quad (32)$$

or

$$\begin{aligned} \hat{x} : \nabla_x \mathcal{L}(\hat{x}, u, k) &= \nabla f(\hat{x}) - \sum_{i=1}^p \psi'(kc_i(\hat{x})) u_i \nabla c_i(\hat{x}) \\ u_i \nabla c_i(\hat{x}) &= 0, \end{aligned}$$

followed by the Lagrange multipliers update by formula

$$\hat{u}_i = \psi'(kc_i(\hat{x})) u_i, i = 1, \dots, p,$$

or

$$\hat{u} = \Psi'(kc(\hat{x})) u, \quad (33)$$

where $\Psi'(kc(x)) = \text{diag}(\psi'(kc_i(x)))_{i=1}^p$, and scaling parameter update by formula

$$\hat{k} := v(\hat{x}, \hat{u})^{-0.5}. \quad (34)$$

In other words, for a given Lagrange multipliers vector $u \in \mathbb{R}_{++}^p$ and the scaling

parameter $k > 0$, one step of the NR method is equivalent to solving the following nonlinear PD system:

$$\begin{aligned} \nabla_x \mathcal{L}(\hat{x}, u, k) &= \nabla f(\hat{x}) - \sum_{i=1}^p \psi'(kc_i(\hat{x})) u_i \nabla c_i(\hat{x}) \\ &= \nabla_x L(\hat{x}, \hat{u}) = 0, \end{aligned} \quad (35)$$

$$\hat{u} = \Psi'(kc(\hat{x})) u, \quad (36)$$

for $\hat{x}$ and $\hat{u}$, followed by the scaling parameter $k > 0$ update by Equation (34).

Application of Newton's method for solving the nonlinear PD system (35)–(36) for $\hat{x}$ and $\hat{u}$ leads to the primal-dual nonlinear rescaling (PDNR) method for solving (ICCO) problem [20].

By linearizing Equations (35)–(36) and assuming that $\bar{u} = \Psi'(kc(x)) u$, we obtain the following linear PD system for finding the Newton direction $(\Delta x, \Delta u)$:

$$\begin{bmatrix} \nabla_{xx}^2 L(\cdot) & -\nabla c^T(\cdot) \\ -U \Psi''(\cdot) \nabla c(\cdot) & \frac{1}{k} I_p \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta u \end{bmatrix} = \begin{bmatrix} -\nabla_x L(\cdot) \\ \frac{1}{k} (\bar{u} - u) \end{bmatrix}, \quad (37)$$

where $\nabla c(\cdot) = \nabla c(x)$, $\Psi'(\cdot) = \Psi'(kc(x)) = \text{diag}(\psi''(kc_i(x)))_{i=1}^p$, $U = \text{diag}(u_i)_{i=1}^p$ and I_p is an identity matrix in $\mathbb{R}^p$.

Let $\delta > 0$ be small enough and $0 < \epsilon \ll \delta$ be the desired accuracy. Then for a given $x \in \mathbb{R}^n$, Lagrange multipliers vector $u \in \mathbb{R}_{++}^p$, and scaling parameter $k > 0$, one step of the PDNR method consists of the following operations:

PDNRM - Primal-Dual Nonlinear Rescaling Method

Step 0. Let $y = (x, u) \in S(y^*, \delta)$.

Step 1. If $v(y) \leq \epsilon$, then output y as a solution.

Step 2. Set $k = v(x, u)^{-0.5}$.

Step 3. Find Δx and Δu from (37).

Step 4. Update the primal-dual pair by the formulas

$$\hat{x} := x + \Delta x, \quad \hat{u} := u + \Delta u.$$

Step 5. Goto Step 1.

If the standard second-order optimality conditions are satisfied, the Lipschitz conditions for the Hessians $\nabla^2 f(x)$, $\nabla^2 c_i$, $i = 1, \dots, p$ hold, and $y = (x, u) \in S(y^*, \delta)$, then the PDNR algorithm generates a PD sequence that converges to the PD solution with 1.5-Q-superlinear rate. A small modification of the PDNR algorithm generates a PD sequence that converges from any starting point $y = (x, u) \in \mathbb{R}^n \times \mathbb{R}_{++}^p$ with asymptotic 1.5-Q-superlinear rate [20].

PRIMAL-DUAL EXTERIOR-POINT METHOD FOR INEQUALITY CONSTRAINED OPTIMIZATION

Due to properties 1⁰ and 2⁰ for any given vector $k = (k_1, \dots, k_p) \in \mathbb{R}_{++}^p$, we have

$$c_i(x) \geq 0 \iff k_i \psi(k_i c_i(x)) \geq 0, \quad i = 1, \dots, p.$$

Consider the Lagrangian $\mathcal{L} : \mathbb{R}^n \times \mathbb{R}_+^p \times \mathbb{R}_{++}^p \rightarrow \mathbb{R}$

$$\mathcal{L}(x, u, \mathbf{k}) = f(x) - \sum_{i=1}^p k_i^{-1} u_i \psi(k_i c_i(x))$$

for the equivalent problem. Let $k > 0$, $x \in \mathbb{R}^n$, $u \in \mathbb{R}^p$ and $\mathbf{k} = (k_i = k(u_i)^{-1}, i = 1, \dots, p)$.

One step of the NR method with “dynamic” scaling parameters update maps the given triple $(x, u, \mathbf{k}) \in \mathbb{R}^n \times \mathbb{R}_+^p \times \mathbb{R}_{++}^p$ into the triple $(\hat{x}, \hat{u}, \hat{\mathbf{k}}) \in \mathbb{R}^n \times \mathbb{R}_+^p \times \mathbb{R}_{++}^p$ defined by formulas

$$\begin{aligned} \hat{x} &: \nabla_x \mathcal{L}(\hat{x}, u, \mathbf{k}) \\ &= \nabla f(\hat{x}) - \sum_{i=1}^p \psi'(k_i c_i(\hat{x})) u_i \nabla c_i(\hat{x}) \\ &= \nabla f(\hat{x}) - \sum_{i=1}^p \hat{u}_i \nabla c_i(\hat{x}), \end{aligned} \quad (38)$$

$$\hat{u} : \hat{u}_i = u_i \psi'(k_i c_i(\hat{x})), \quad i = 1, \dots, p, \quad (39)$$

$$\hat{\mathbf{k}} : \hat{k}_i = k \hat{u}_i^{-1}, \quad i = 1, \dots, p. \quad (40)$$

Such a method was considered in Ref. 18 for exponential transformation ψ_1 . By removing the formula for the scaling vector update (40)

from the system (38), (39), (40) we obtain the following nonlinear PD system:

$$\nabla_x L(\hat{x}, \hat{u}) = \nabla f(\hat{x}) - \sum_{i=1}^p \hat{u}_i \nabla c_i(\hat{x}), \quad (41)$$

$$\hat{u} = \Psi'(k c(\hat{x})) u, \quad (42)$$

where $\Psi'(k c(\hat{x})) = \text{diag}(\psi'(k_i c_i(\hat{x})))_{i=1}^p$. To measure the distance between the current approximation $y = (x, u)$ and the solution y^* , the merit function (31) is used.

Due to Equation (40), the Lagrange multipliers that correspond to the passive constraints (LMPC) converge to zero with at least a quadratic rate. Therefore, for $0 < \epsilon \ll 1$, it requires at most $s = \mathcal{O}(\ln \ln \epsilon^{-1})$ Lagrange multipliers updates for the LMPC to become of the order of $\mathcal{O}(\epsilon^2)$. So the PD system (41), (42) is reduced to the following nonlinear PD system:

$$\nabla_x L(\hat{x}, \hat{u}) = \nabla f(\hat{x}) - \sum_{i=1}^r \hat{u}_i \nabla c_i(\hat{x}), \quad (43)$$

$$\hat{u}_i = u_i \psi'(k_i c_i(\hat{x})), \quad i = 1, \dots, r, \quad (44)$$

where $I^* = \{i : c_i(x^*) = 0\} = \{1, \dots, r\}$.

Application of Newton’s method for solving the PD system (43), (44) leads to a local PDEP method for (ICCO) problems. Start with linearization of the system (44); due to the property 2⁰ of the transformation $\psi \in \Psi$, the inverse ψ'^{-1} exists. Therefore using the identity $\psi'^{-1} = \psi'^*$, where $\psi^*(s) = \inf_t \{st - \psi(t) | t \in \mathbb{R}\}$ is the conjugate of ψ , and denoting $\varphi = -\psi^*$, we can rewrite Equation (44) as follows:

$$\begin{aligned} c_i(\hat{x}) &= k^{-1} u_i \psi'^{-1} \left(\frac{\hat{u}_i}{u_i} \right) = k^{-1} u_i \psi'^* \left(\frac{\hat{u}_i}{u_i} \right) \\ &= -k^{-1} u_i \varphi' \left(\frac{\hat{u}_i}{u_i} \right). \end{aligned}$$

It follows from property 3⁰ of transformation ψ that $\varphi'(1) = 0$. Assuming $\hat{x} = x + \Delta x$ and $\hat{u} = u + \Delta u$, and ignoring terms of the second and higher order, we obtain

$$c_i(\hat{x}) = c_i(x) + \nabla c_i(x) \Delta x$$

$$\begin{aligned}
&= -k^{-1}u_i\varphi'\left(\frac{u_i + \Delta u_i}{u_i}\right) \\
&= -k^{-1}u_i\varphi'\left(1 + \frac{\Delta u_i}{u_i}\right) = -k^{-1}\varphi''(1)\Delta u_i, \\
&i = 1, \dots, r,
\end{aligned}$$

or

$$\begin{aligned}
&c_i(x) + \nabla c_i(x)\Delta x + k^{-1}\varphi''(1)\Delta u_i = 0, \\
&i = 1, \dots, r.
\end{aligned}$$

By linearizing the system (43) at $y = (x, u)$, we obtain the following linear PD system for

finding the PD Newton directions:

$$\begin{bmatrix} \nabla_{xx}L(\cdot) & -\nabla c^T(\cdot) \\ \nabla c(\cdot) & k^{-1}\varphi''(1)I_r \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta u \end{bmatrix} = \begin{bmatrix} \nabla_x L(\cdot) \\ -c(\cdot) \end{bmatrix} \quad (45)$$

where I_r is the identity matrix in $\mathbb{R}^r$ and $\nabla c(x) = J(c(x))$ is the Jacobian of the vector function $c(x)$.

Let $\delta > 0$ be small enough and $0 < \epsilon \ll \delta$ be the desired accuracy. Then the PDEP method for (ICCO) problems consists of the following operations.

PDEPICOM - Primal-Dual Exterior-Point Method for ICCO

- Step 0. Let $y = (x, u) \in S(y^*, \delta)$.
Step 1. If $v(y) \leq \epsilon$, then output y as a solution.
Step 2. Set $k = v(x, u)^{-1}$.
Step 3. Find Δx and Δu from (45).
Step 4. Update the primal-dual pair by the formulas

$$\hat{x} := x + \Delta x, \quad \hat{u} := u + \Delta u.$$

Step 5. Goto Step 1.

Under the standard second-order optimality conditions and Lipschitz conditions for the Hessians $\nabla^2 f(x)$, $\nabla^2 c_i$, $i = 1, \dots, r$, the PDEP algorithm generates a PD sequence that converges to the PD solution $y^* = (x^*, u^*)$ with quadratic rate. The globally convergent PDEP method with an asymptotic quadratic rate is given in [21].

PRIMAL-DUAL EXTERIOR-POINT METHOD FOR OPTIMIZATION PROBLEMS WITH BOTH EQUALITY AND INEQUALITY CONSTRAINTS

Consider $p + q + 1$ twice continuously differential functions $f, c_i, g_j: \mathbb{R}^n \rightarrow \mathbb{R}$, $i = 1, \dots, p, j = 1, \dots, q$ and the feasible set

$$\begin{aligned}
\Omega = \{x : c_i(x) \geq 0, i = 1, \dots, p; \\
g_j(x) = 0, j = 1, \dots, q\}.
\end{aligned}$$

The problem with both inequality and equality constraints consists of finding

$$(\mathcal{IECO}) \quad f(x^*) = \min\{f(x) | x \in \Omega\}.$$

We use $\psi \in \Psi$ to transform the inequality constraints $c_i(x) \geq 0$, $i = 1, \dots, p$ into an equivalent set of constraints. For any fixed $k > 0$, the following problem is equivalent to the original (IECO) problem due to the properties of $\psi \in \Psi$; that is,

$$\begin{aligned}
f(x^*) &= \min\{f(x) | k^{-1}\psi(kc_i(x)) \geq 0, \\
&i = 1, \dots, p; g_j(x) = 0, j = 1, \dots, q\}.
\end{aligned}$$

For a given $k > 0$, the AL $\mathcal{L}_k: \mathbb{R}^n \times \mathbb{R}_+^p \times \mathbb{R}^q \rightarrow \mathbb{R}^1$ for the equivalent problem is defined by the formula

$$\begin{aligned}
\mathcal{L}_k(x, u, v) &= f(x) - k^{-1} \sum_{i=1}^p u_i \psi(kc_i(x)) \\
&- \sum_{j=1}^q v_j g_j(x) + \frac{k}{2} \sum_{j=1}^q g_j^2(x). \quad (46)
\end{aligned}$$

The first two terms define the classical Lagrangian for the equivalent problem in the absence of equality constraints. The last two

terms coincide with the AL terms associated with equality constraints.

For a given $k > 0$ and $y = (x, u, v) \in S(y^*, \delta)$, a step of nonlinear rescaling-AL method maps the triple $y = (x, u, v)$ into the triple $\hat{y} = (\hat{x}, \hat{u}, \hat{v})$, where

$$\hat{x} = \arg \min_{x \in \mathbb{R}^n} \mathcal{L}_k(x, u, v), \quad (47)$$

or

$$\begin{aligned} \hat{x} : \nabla f(\hat{x}) - \sum_{i=1}^p u_i \psi'(kc_i(\hat{x})) \nabla c_i(\hat{x}) \\ - \sum_{j=1}^q (v_j - kg_j(\hat{x})) \nabla g_j(\hat{x}) = 0, \end{aligned} \quad (48)$$

$$\hat{u}_i = u_i \psi'(kc_i(\hat{x})), \quad i = 1, \dots, p; \quad (49)$$

$$\hat{v}_j = v_j - kg_j(\hat{x}), \quad j = 1, \dots, q. \quad (50)$$

The system (48)–(50) can be replaced by the following nonlinear PD system:

$$\begin{aligned} \nabla_x L(\hat{x}, \hat{u}, \hat{v}) = \nabla f(\hat{x}) - \sum_{i=1}^p \hat{u}_i \nabla c_i(\hat{x}) \\ - \sum_{j=1}^q \hat{v}_j \nabla g_j(\hat{x}) = 0, \end{aligned} \quad (51)$$

$$\hat{u} - \Psi'(kc(\hat{x})) u = 0, \quad (52)$$

$$\hat{v} - v + kg(\hat{x}) = 0, \quad (53)$$

where $\Psi'(kc(\hat{x})) = \text{diag}(\psi'(kc_i(\hat{x})))_{i=1}^p$.

We use the following merit function:

PDEPM - Primal-Dual Exterior-Point Method

Step 0. Let $y \in S(y^*, \delta)$.

Step 1. If $\mu(y) \leq \epsilon$, then output y as a solution.

Step 2. Set $k = v(x, u, v)^{-0.5}$.

Step 3. Find Δx , Δu , and Δv from Equation (55).

Step 4. Update the primal-dual pair by the formulas

$$\hat{x} := x + \Delta x, \quad \hat{u} := u + \Delta u, \quad \hat{v} := v + \Delta v.$$

Step 5. Goto Step 1.

$$v(y) = v(x, u, v)$$

$$= \max\{\|\nabla_x L(x, u, v)\|, \quad - \min_{1 \leq i \leq p} c_i(x),$$

$$\max_{1 \leq i \leq q} |g_i(x)|, \quad \sum_{i=1}^p |u_i| |c_i(x)|, \quad - \min_{1 \leq i \leq p} u_i\}. \quad (54)$$

Under the standard second-order optimality conditions, $v(y)$ possesses properties (7), (8).

Application of Newton's method to the system (51), (52), (53) for $\hat{x}$, $\hat{u}$, and $\hat{v}$ from the starting point $y = (x, u, v) \in S(y^*, \delta)$ leads to the PD exterior-point method (PDEPM) [22]. By linearizing the system (51), (52), (53) and ignoring terms of the second and higher order, we obtain the following linear PD system for finding the Newton direction $\Delta y = (\Delta x, \Delta u, \Delta v)$:

$$\begin{bmatrix} \nabla_{xx}^2 L(\cdot) & -\nabla c^T(\cdot) & -\nabla g^T(\cdot) \\ -U \Psi''(\cdot) \nabla c(\cdot) & \frac{1}{k} I_p & 0 \\ \nabla g(\cdot) & 0 & \frac{1}{k} I_q \end{bmatrix} \times \begin{bmatrix} \Delta x \\ \Delta u \\ \Delta v \end{bmatrix} = \begin{bmatrix} -\nabla_x L(\cdot) \\ \frac{1}{k} (\bar{u} - u) \\ -g(\cdot) \end{bmatrix}, \quad (55)$$

where $\nabla c(\cdot) = \nabla c(x)$, $\nabla g(\cdot) = \nabla g(x)$, $\Psi'(\cdot) = \Psi'(kc(x)) = \text{diag}(\psi'(kc_i(x)))_{i=1}^p$, $\bar{u} = \Psi'(kc(x))u$, $U = \text{diag}(u_i)_{i=1}^p$, and I_p , I_q are the identity matrices in $\mathbb{R}^p$ and $\mathbb{R}^q$ respectively.

The PD exterior-point method for constrained optimization problems with both inequality and equality constraints consists of the following operations.

Under the standard second-order optimality conditions and Lipschitz conditions for the Hessians $\nabla^2 f(x)$, $\nabla^2 c_i$, $i = 1, \dots, m$, $\nabla^2 g_i$, $i = 1, \dots, q$, for any $y \in S(y^*, \delta)$, the PDEPM algorithm generates the PD sequence that converges to the PD solution with 1.5-Q-superlinear rate [22].

CONCLUDING REMARKS

As we have seen, any PD method for constrained optimization is associated with particular PD nonlinear system of equations. Application of Newton's method to the system is equivalent to one step of either an interior- or an exterior-point method. Therefore, the computational process is defined by a particular PD nonlinear system and excellent convergence properties of Newton's method. As a result, under the standard second-order optimality conditions, the PD methods generate sequences that converge to the PD solution with an asymptotic quadratic rate.

As a practical matter it is worth mentioning that in the neighborhood of the solution the PD interior-point method generates a sequence similar to that generated by Newton's method for solving KKT's system, while the PD exterior-point method generates a sequence similar to that generated by Newton's method for solving the Lagrange system of equations that correspond to the active constraints. Unlike the former nonlinear system, the latter system does not contain complementarity equations. Therefore, the practical PD exterior-point method often is capable of finding the PD solution with a very high of accuracy.

PROBABILISTIC DISTANCE CLUSTERING

CEM IYIGUN

Department of Industrial Engineering,
Middle East Technical University,
Ankara, Turkey

INTRODUCTION

A *cluster* is a set of data points (patterns, observations) that are similar in some sense and *clustering* is a process of organizing a collection of data items (data set) into disjoint clusters. The items within a cluster are more *similar* to each other than to the items in other clusters. The *similarity* term can be expressed in very different ways, based on the context and the purpose of the study [38].

Clustering is a basic tool in *statistics* [2] and *machine learning* [3], and has been applied in *pattern recognition*, *medical diagnostics*, *operations research* [4], *data mining* [5], biology, finance, and also in applied areas including genetics, taxonomy, medicine, marketing, and e-commerce (see Refs 6 and 7 for applications of clustering).

It is useful to begin by reviewing various issues in clustering analysis and then we introduce our notation and terminology that is used throughout the paper.

Generally, clustering is called *unsupervised learning* because unlike classification (known as *supervised learning*), it is performed when no prior information is available concerning the membership of data items for categorizing them to predefined classes. Besides, the traditional definition of clustering, in some recent studies called *semisupervised clustering*, a small amount of information is used to guide or adjust the clustering structure [8] and [9].

Clustering aims at exploring relationships among a collection of data points and organizing them into disjoint clusters. Two basic

measures, *similarity* in a cluster and *dissimilarity* between clusters, are considered while creating clusters. Similarity in a cluster, called *intraconnectivity*, measures the density of connections between data points of a single cluster. In a good clustering arrangement, since the data points within the same cluster are highly similar to each other, the value of the intraconnectivity will be high, whereas dissimilarity between clusters, called *interconnectivity*, measures the connectivity between distinct clusters. A low degree of interconnectivity is aimed at because it indicates that individual clusters are largely dissimilar to each other.

The objects of clustering are *data points* (also *observations*, or *instances*). Each data point is an ordered list of *attributes* (or *features*), such as height, age, and ID number. In a given collection of data points, named a *data set*, every data point is represented by using the same set of *attributes* (features). The attributes can be in the form of *continuous*, *categorical* or *binary* data [10].

The interpretation of clusters is a difficult task. The *number of clusters* is given, however in many applications, the “right” number of clusters (to fit best the data) needs to be determined. Even if there were no cluster structure in a given data set the algorithm will always assign the data points to clusters and form a clustering structure. Therefore, if the goal is to draw conclusions about the cluster structure in a data set, it is essential to analyze whether the data set has a clustering tendency. Another problem that one can face in clustering is the quality of the data. In many applications, there may be missing values or errors in the data set due to inaccurate measurement. So a strategy needs to be chosen for handling missing values, see Ref. 11. A preprocessing stage may also be needed to organize the data before the analysis. *Feature selection*, *aggregation*, and *dimensionality reduction* are some of the common preprocessing methods used.

Clustering is a difficult problem due to

many factors. How to process and prepare the data, which similarity measures are effective, which algorithm is appropriate, and how sensitive the algorithm output is to initial conditions are the questions that a clustering method needs to deal with [12]. These factors come into play in devising a well-tuned clustering technique for a given clustering problem. Moreover, there is no technique that is applicable to all sorts of cluster structures.

Clustering algorithms can be categorized into *partitioning (center-based)*, *hierarchical*, *density-based*, *grid-based*, and *model-based methods*. An excellent survey of clustering techniques can be found in Ref. 12. Some more recent works in clustering techniques can also be found in Ref. 13. In each of the clustering categories listed above, there are many papers in the literature that describe different algorithms and relevant work. For comprehensive explanations and further details, the reader can see Refs 14–16 for partitioning methods; Refs 2, 17, and 18 for hierarchical methods; Refs 19, 20 for density-based methods, and Refs 21, 22 for model-based methods.

Notation and Terminology

We take data points to be vectors $\mathbf{x} = (x_1, \dots, x_n) \in \mathbb{R}^n$, and interpret “similar” as “close,” in terms of a *distance* function $d(\mathbf{x}, \mathbf{y})$ in $\mathbb{R}^n$, such as

$$d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|, \forall \mathbf{x}, \mathbf{y} \in \mathbb{R}^n, \quad (1)$$

where the norm $\|\cdot\|$ is *elliptic*, defined for $\mathbf{u} = (u_i)$ by

$$\|\mathbf{u}\| = \langle \mathbf{u}, Q\mathbf{u} \rangle^{1/2}, \quad (2)$$

with $\langle \cdot, \cdot \rangle$ the standard inner product, and Q a positive definite matrix. In particular, $Q = I$ gives the *Euclidean norm*,

$$\|\mathbf{u}\| = \langle \mathbf{u}, \mathbf{u} \rangle^{1/2}, \quad (3)$$

and the *Mahalanobis distance* corresponds to $Q = \Sigma^{-1}$, where Σ is the covariance matrix of the data involved.

Example 1. A data set in $\mathbb{R}^2$ with $N = 200$ data points is shown in Figure 1. The data

was simulated, from normal distributions $N(\mu_i, \Sigma_i)$, with

$$\mu_1 = (0, 0), \Sigma_1 = \begin{pmatrix} 0.1 & 0 \\ 0 & 1 \end{pmatrix}, (100 \text{ points}),$$

$$\mu_2 = (3, 0), \Sigma_2 = \begin{pmatrix} 1 & 0 \\ 0 & 0.1 \end{pmatrix}, (100 \text{ points}).$$

This data will serve to illustrate Examples 2–5 below.

The *clustering problem* is, given a *data set* $\mathcal{D}$ consisting of N data points

$$\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\} \subset \mathbb{R}^n,$$

and an integer K , $1 < K < N$, to partition $\mathcal{D}$ into K clusters $\mathcal{C}_1, \dots, \mathcal{C}_K$.

Data points are assigned to clusters using a *clustering criterion*. In *distance clustering*, abbreviated *d-clustering*, the clustering criterion is metric: with each cluster $\mathcal{C}_k$ we associate a *center* $\mathbf{c}_k$, for example its centroid, and each data point is assigned to the cluster to whose center it is the nearest. After each such assignment, the cluster centers may change, resulting in reassignments. Such an algorithm will therefore iterate between updating the centers and reassignments.

A commonly used clustering criterion is the sum-of-squares of Euclidean distances,

$$\sum_{k=1}^K \sum_{\mathbf{x}_i \in \mathcal{C}_k} \|\mathbf{x}_i - \mathbf{c}_k\|^2, \quad (4)$$

to be minimized by the sought clusters $\mathcal{C}_1, \dots, \mathcal{C}_K$. The well known *k-means clustering algorithm* [14] uses this criterion.

In *probabilistic clustering* the assignment of points to clusters is “soft,” in the sense that the membership of a data point $\mathbf{x}$ in a cluster $\mathcal{C}_k$ is given as a *probability*, denoted by $p_k(\mathbf{x})$. These are subjective probabilities, indicating strength of belief in the event in question.

Let a *distance function*

$$d_k(\cdot, \cdot) \quad (5)$$

be defined for each cluster $\mathcal{C}_k$. These distance functions are, in general, different from one

Figure 1. A data set in $\mathbb{R}^2$.

cluster to another. For each data point $\mathbf{x} \in \mathcal{D}$, we then compute:

- the *distance* $d_k(\mathbf{x}, \mathbf{c}_k)$, also denoted by $d_k(\mathbf{x})$ (since d_k is used only for distances from $\mathbf{c}_k$), or just d_k if $\mathbf{x}$ is understood, and
- a *probability* that $\mathbf{x}$ is a member of C_k , denoted by $p_k(\mathbf{x})$, or just p_k .

Various relations between probabilities and distances can be assumed, resulting in different ways of clustering the data. In our experience, the following assumption has proved useful: for any point $\mathbf{x}$, and all $k = 1, \dots, K$

$$p_k(\mathbf{x}) d_k(\mathbf{x}) = \text{constant, depending on } \mathbf{x}.$$

This model is our working *principle* in what follows, and the basis of the *probabilistic d-clustering* [1], approach of the following section.

The above principle owes its versatility to the different ways of choosing the distances $d_k(\cdot)$. It is also natural to consider increasing functions of such distances, and one useful choice is

$$p_k(\mathbf{x}) e^{d_k(\mathbf{x})} = \text{constant, depending on } \mathbf{x},$$

giving the *probabilistic exponential d-clustering*.

The probabilistic d-clustering algorithm is presented in the following sections. It is a generalization, to several centers, of the Weiszfeld method for solving the Fermat–Weber location problem, and convergence follows as in Ref. 23. The updates of the centers use an extremal principle. The progress of the algorithm is monitored by the *joint distance function* (JDF), a distance function that captures the data in its low contours. The centers updated by the algorithm are stationary points of the joint distance function.

In the final part of the paper, a new function, *classification uncertainty function*, is introduced whose values indicate the uncertainty of classifying a data point to one of the clusters. The paper concludes with the problem of determining the “right” number of clusters in a given data set, using the classification of uncertainty function.

For other approaches to probabilistic clustering, see the surveys in Refs 11 and 24, and the seminal article [25] unifying clustering methods in the framework of modern optimization theory.

PROBABILISTIC D-CLUSTERING

There are several ways to model the relationship between distances and probabilities. The

simplest model, and our working *principle* (or axiom), is the following:

Principle 1. For each $\mathbf{x} \in \mathcal{D}$, and each cluster C_k ,

$$p_k(\mathbf{x})d_k(\mathbf{x}) = \text{constant, depending on } \mathbf{x}. \quad (6)$$

Cluster membership is thus more probable the closer the data point is to the cluster center. Note that the constant in Equation (6) is independent of the cluster k .

Probabilities

From Principle 1, and the fact that probabilities add to one, we get the following.

Theorem 1. Let the cluster centers $\{\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_K\}$ be given, let $\mathbf{x}$ be a data point, and let $\{d_k(\mathbf{x}) : k = 1, \dots, K\}$ be its distances from the given centers. Then the membership probabilities of $\mathbf{x}$ are

$$p_k(\mathbf{x}) = \frac{\prod_{j \neq k} d_j(\mathbf{x})}{\sum_{t=1}^K \prod_{j \neq t} d_j(\mathbf{x})}, \quad k = 1, \dots, K. \quad (7)$$

Proof. Using Equation (6) we write for t, k

$$p_t(\mathbf{x}) = \left(\frac{p_k(\mathbf{x})d_k(\mathbf{x})}{d_t(\mathbf{x})} \right).$$

Since $\sum_{t=1}^K p_t(\mathbf{x}) = 1$,

$$p_k(\mathbf{x}) \sum_{t=1}^K \left(\frac{d_k(\mathbf{x})}{d_t(\mathbf{x})} \right) = 1.$$

$$\therefore p_k(\mathbf{x}) = \frac{1}{\sum_{t=1}^K \left(\frac{d_k(\mathbf{x})}{d_t(\mathbf{x})} \right)} = \frac{\prod_{j \neq k} d_j(\mathbf{x})}{\sum_{t=1}^K \prod_{j \neq t} d_j(\mathbf{x})}.$$

In particular, for $K = 2$,

$$\begin{aligned} p_1(\mathbf{x}) &= \frac{d_2(\mathbf{x})}{d_1(\mathbf{x}) + d_2(\mathbf{x})}, \\ p_2(\mathbf{x}) &= \frac{d_1(\mathbf{x})}{d_1(\mathbf{x}) + d_2(\mathbf{x})}, \end{aligned} \quad (8)$$

and for $K = 3$,

$$\begin{aligned} p_1(\mathbf{x}) &= \frac{d_2(\mathbf{x})d_3(\mathbf{x})}{d_1(\mathbf{x})d_2(\mathbf{x}) + d_1(\mathbf{x})d_3(\mathbf{x}) + d_2(\mathbf{x})d_3(\mathbf{x})}, \text{ etc.} \\ & \quad (9) \end{aligned}$$

Note: See Ref. 26 for related work in a different context. In particular, our Equation (8) is closely related to Ref. 26, Equation (5).

The Joint Distance Function

We denote the constant in Equation (6) by $D(\mathbf{x})$, a function of $\mathbf{x}$. Then

$$p_k(\mathbf{x}) = \frac{D(\mathbf{x})}{d_k(\mathbf{x})}, \quad k = 1, \dots, K.$$

Since the probabilities add to one we get,

$$D(\mathbf{x}) = \frac{\prod_{k=1}^K d_k(\mathbf{x}, \mathbf{c}_k)}{\sum_{t=1}^K \prod_{j \neq t} d_j(\mathbf{x}, \mathbf{c}_j)}. \quad (10)$$

The function $D(\mathbf{x})$, called the *JDF* of $\mathbf{x}$, has the dimension of distance, and measures the distance of $\mathbf{x}$ from all cluster centers. Here are special cases of Equation (10), for $K = 2$,

$$D(\mathbf{x}) = \frac{d_1(\mathbf{x})d_2(\mathbf{x})}{d_1(\mathbf{x}) + d_2(\mathbf{x})}, \quad (11)$$

and for $K = 3$,

$$D(\mathbf{x}) = \frac{d_1(\mathbf{x})d_2(\mathbf{x})d_3(\mathbf{x})}{d_1(\mathbf{x})d_2(\mathbf{x}) + d_1(\mathbf{x})d_3(\mathbf{x}) + d_2(\mathbf{x})d_3(\mathbf{x})}. \quad (12)$$

The JDF of the whole data set $\mathcal{D}$ is the sum of Equation (10) over all points, and is a

Figure 2. Level sets of a joint distance function.

function of the K cluster centers, say,

$$F(\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_K) = \sum_{i=1}^N \frac{\prod_{k=1}^K d_k(\mathbf{x}_i, \mathbf{c}_k)}{\sum_{t=1}^N \prod_{j \neq t} d_j(\mathbf{x}_i, \mathbf{c}_j)}. \quad (13)$$

Example 2. Figure 2 shows level sets of the JDF (Eq. 11), with Mahalanobis distances

$$d_k(\mathbf{x}, \mathbf{c}_k) = \sqrt{(\mathbf{x} - \mathbf{c}_k)^T \Sigma_k^{-1} (\mathbf{x} - \mathbf{c}_k)}, \quad (14)$$

$\mathbf{c}_1 = \mu_1, \mathbf{c}_2 = \mu_2$, and Σ_1, Σ_2 as in Example 1.

Notes:

- (a) The JDF $D(\mathbf{x})$ of Equation (10) is a measure of the classifiability of the point $\mathbf{x}$ in question. It is zero if and only if $\mathbf{x}$ coincides with one of the cluster centers, in which case $\mathbf{x}$ belongs to that cluster with probability 1. If all the distances $d_k(\mathbf{x}, \mathbf{c}_k)$ are equal, say equal to d , then $D(\mathbf{x}) = d/k$ and all $p_k(\mathbf{x}) = 1/K$, showing indifference between the clusters. As the distances $d_k(\mathbf{x})$ increase, so does $D(\mathbf{x})$, indicating greater uncertainty about the cluster where $\mathbf{x}$ belongs.

- (b) The JDF (Eq. 10) is, up to a constant, the *harmonic mean* of the distances involved, see Ref. 27 for an elucidation of the role of the harmonic mean in contour approximation of data. A related concept in ecology is the *home range*, shown in Ref. 28 to be the harmonic mean of the area moments in question.

An Extremal Principle

For simplicity, consider the case of two clusters (the results are easily extended to the general case).

Let $\mathbf{x}$ be a given data point with distances $d_1(\mathbf{x}), d_2(\mathbf{x})$ to the cluster centers. Then the probabilities in Equation (8) are the optimal solutions p_1, p_2 of the extremal problem

$$\begin{aligned} &\text{Minimize} && d_1(\mathbf{x})p_1^2 + d_2(\mathbf{x})p_2^2 \\ &\text{subject to} && p_1 + p_2 = 1 \\ &&& p_1, p_2 \geq 0. \end{aligned} \quad (15)$$

Indeed, the *Lagrangian* of this problem is

$$\begin{aligned} L(p_1, p_2, \lambda) &= d_1(\mathbf{x})p_1^2 + d_2(\mathbf{x}) \\ &\quad \times p_2^2 - \lambda(p_1 + p_2 - 1), \end{aligned} \quad (16)$$

and setting the partial derivatives (with respect to p_1, p_2) equal to zero gives the

principle (Eq. 6)

$$p_1 d_1(\mathbf{x}) = p_2 d_2(\mathbf{x}).$$

Substituting the probabilities (Eq. 8) in the Lagrangian (Eq. 16) we get the optimal value of Equation (15)

$$L^*(p_1(\mathbf{x}), p_2(\mathbf{x}), \lambda) = \frac{d_1(\mathbf{x})d_2(\mathbf{x})}{d_1(\mathbf{x}) + d_2(\mathbf{x})}, \quad (17)$$

which is the JDF (Eq. 11) again.

The extremal problem for a data set $\mathcal{D} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\} \subset \mathbb{R}^n$ is, accordingly,

$$\begin{aligned} & \text{Minimize } \sum_{i=1}^N \left(d_1(\mathbf{x}_i) p_1(\mathbf{x}_i)^2 + d_2(\mathbf{x}_i) p_2(\mathbf{x}_i)^2 \right) \\ & \text{subject to } p_1(\mathbf{x}_i) + p_2(\mathbf{x}_i) = 1 \\ & \quad p_1(\mathbf{x}_i), p_2(\mathbf{x}_i) \geq 0, \quad i = 1, \dots, N. \end{aligned} \quad (18)$$

This problem separates into N problems like Equation (15), and its optimal value is

$$\sum_{i=1}^N \frac{d_1(\mathbf{x}_i) d_2(\mathbf{x}_i)}{d_1(\mathbf{x}_i) + d_2(\mathbf{x}_i)}, \quad (19)$$

the JDF (Eq. 13) of the data set, with $K = 2$. *Note:* The explanation for the strange appearance of “probabilities squared” above, is that Equation (15) is a smoothed version of the “real” clustering problem, namely,

$$\min \{d_1, d_2\},$$

which is nonsmooth; see Ref. 25 for a unified development of smoothed clustering methods.

Centers

We write Equation (18) as a function of the cluster centers $\mathbf{c}_1, \mathbf{c}_2$,

$$\begin{aligned} f(\mathbf{c}_1, \mathbf{c}_2) = \sum_{i=1}^N & \left(d_1(\mathbf{x}_i, \mathbf{c}_1) p_1(\mathbf{x}_i)^2 \right. \\ & \left. + d_2(\mathbf{x}_i, \mathbf{c}_2) p_2(\mathbf{x}_i)^2 \right). \end{aligned} \quad (20)$$

If a point $\mathbf{x}_i$ coincides with a center, say $\mathbf{x}_i = \mathbf{c}_1$, then $d_1(\mathbf{x}_i) = 0$, $p_1(\mathbf{x}_i) = 1$, and $p_2(\mathbf{x}_i) = 0$. This point contributes zero to the summation.

For the special case of Euclidean distances, the minimizers of Equation (20) assume a simple form as convex combinations of the data points.

Theorem 2. *Let the distance functions d_1, d_2 in Equation (20) be Euclidean,*

$$d_k(\mathbf{x}, \mathbf{c}_k) = \|\mathbf{x} - \mathbf{c}_k\|, \quad k = 1, 2, \quad (21)$$

so that

$$\begin{aligned} f(\mathbf{c}_1, \mathbf{c}_2) = \sum_{i=1, \dots, N} & \left(\|\mathbf{x}_i - \mathbf{c}_1\| p_1(\mathbf{x}_i)^2 \right. \\ & \left. + \|\mathbf{x}_i - \mathbf{c}_2\| p_2(\mathbf{x}_i)^2 \right), \end{aligned} \quad (22)$$

and let the probabilities $p_1(\mathbf{x}_i), p_2(\mathbf{x}_i)$ be given for $i = 1, \dots, N$. We make the following assumption about the minimizers $\mathbf{c}_1, \mathbf{c}_2$ of Equation (22):

$$\begin{aligned} & \mathbf{c}_1, \mathbf{c}_2 \text{ do not coincide with any of the points} \\ & \mathbf{x}_i, i = 1, \dots, N. \end{aligned} \quad (23)$$

Then the minimizers $\mathbf{c}_1, \mathbf{c}_2$ are given by

$$\mathbf{c}_k = \sum_{i=1, \dots, N} \left(\frac{u_k(\mathbf{x}_i)}{\sum_{j=1, \dots, N} u_k(\mathbf{x}_j)} \right) \mathbf{x}_i, \quad (24)$$

where

$$u_k(\mathbf{x}_i) = \frac{p_k(\mathbf{x}_i)^2}{d_k(\mathbf{x}_i, \mathbf{c}_k)}, \quad (25)$$

for $k = 1, 2$, or equivalently, using Equation (8)

$$\begin{aligned} u_1(\mathbf{x}_i) &= \frac{d_2(\mathbf{x}_i, \mathbf{c}_2)^2}{d_1(\mathbf{x}_i, \mathbf{c}_1) (d_1(\mathbf{x}_i, \mathbf{c}_1) + d_2(\mathbf{x}_i, \mathbf{c}_2))^2}, \\ u_2(\mathbf{x}_i) &= \frac{d_1(\mathbf{x}_i, \mathbf{c}_1)^2}{d_2(\mathbf{x}_i, \mathbf{c}_2) (d_1(\mathbf{x}_i, \mathbf{c}_1) + d_2(\mathbf{x}_i, \mathbf{c}_2))^2}. \end{aligned} \quad (26)$$

Proof. The gradient of $d(\mathbf{x}, \mathbf{c}) = \|\mathbf{x} - \mathbf{c}\|$ with respect to $\mathbf{c}$ is, for $\mathbf{x} \neq \mathbf{c}$,

$$\nabla_{\mathbf{c}} \|\mathbf{x} - \mathbf{c}\| = -\frac{\mathbf{x} - \mathbf{c}}{\|\mathbf{x} - \mathbf{c}\|} = -\frac{\mathbf{x} - \mathbf{c}}{d(\mathbf{x}, \mathbf{c})}. \quad (27)$$

By Assumption (23), the gradient of Equation (22) with respect to $\mathbf{c}_k$ is

$$\begin{aligned} \nabla_{\mathbf{c}_k} f(\mathbf{c}_1, \mathbf{c}_2) &= - \sum_{i=1, \dots, N} \frac{\mathbf{x}_i - \mathbf{c}_k}{\|\mathbf{x}_i - \mathbf{c}_k\|} p_k(\mathbf{x}_i)^2 \\ &= - \sum_{i=1, \dots, N} \frac{\mathbf{x}_i - \mathbf{c}_k}{d_k(\mathbf{x}_i, \mathbf{c}_k)} p_k(\mathbf{x}_i)^2, \\ &\quad k = 1, 2. \end{aligned} \quad (28)$$

Setting the gradient equal to zero, and summing like terms, we get

$$\begin{aligned} &\sum_{i=1, \dots, N} \left(\frac{p_k(\mathbf{x}_i)^2}{d_k(\mathbf{x}_i, \mathbf{c}_k)} \right) \\ &= \mathbf{x}_i \left(\sum_{i=1, \dots, N} \frac{p_k(\mathbf{x}_i)^2}{d_k(\mathbf{x}_i, \mathbf{c}_k)} \right) \mathbf{c}_k, \end{aligned} \quad (29)$$

proving Equations (24)–(26).

The same formulas for the centers $\mathbf{c}_1, \mathbf{c}_2$ hold if the norm used in Equation (22) is elliptic.

Corollary 1. *Let the distance functions d_1, d_2 in Equation (20) be elliptic*

$$d_k(\mathbf{x}, \mathbf{c}_k) = \langle (\mathbf{x} - \mathbf{c}_k), \mathbf{Q}_k(\mathbf{x} - \mathbf{c}_k) \rangle^{1/2}, \quad (30)$$

with positive-definite matrices $\mathbf{Q}_k$. Then the minimizers $\mathbf{c}_1, \mathbf{c}_2$ of Equation (20) are given by Equations (24)–(26).

Proof. The gradient of $d(\mathbf{x}, \mathbf{c}) = \langle (\mathbf{x} - \mathbf{c}), \mathbf{Q}(\mathbf{x} - \mathbf{c}) \rangle^{1/2}$ with respect to $\mathbf{c}$ is, for $\mathbf{x} \neq \mathbf{c}$,

$$\nabla_{\mathbf{c}} d(\mathbf{x}, \mathbf{c}) = -\frac{\mathbf{Q}(\mathbf{x} - \mathbf{c})}{d(\mathbf{x}, \mathbf{c})}.$$

Therefore, the analog of Equation (28) is

$$\nabla_{\mathbf{c}_k} f(\mathbf{c}_1, \mathbf{c}_2) = -\mathbf{Q}_k \sum_{i=1, \dots, N} \frac{\mathbf{x}_i - \mathbf{c}_k}{d_k(\mathbf{x}_i, \mathbf{c}_k)} p_k(\mathbf{x}_i)^2, \quad (31)$$

and since $\mathbf{Q}_k$ is nonsingular, it can be “cancelled” when we set the gradient equal to zero. The rest of the proof is as in Theorem 2.

Corollary 1 applies, in particular, to the Mahalanobis distance (Eq. 14)

$$d_k(\mathbf{x}, \mathbf{c}_k) = \sqrt{(\mathbf{x} - \mathbf{c}_k)^T \Sigma_k^{-1} (\mathbf{x} - \mathbf{c}_k)},$$

where Σ_k is the covariance matrix of the cluster $\mathcal{C}_k$.

The formulas (24) and (25) are also valid in the general case of K clusters, where the analog of Equation (20) is

$$f(\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_K) = \sum_{i=1, \dots, N} \sum_{k=1}^K d_k(\mathbf{x}_i, \mathbf{c}_k) p_k(\mathbf{x}_i)^2. \quad (32)$$

Corollary 2. *Let the distance functions d_k in Equation (32) be elliptic, as in Equation (30), and let the probabilities $p_k(\mathbf{x}_i)$ be given. Then, the minimizers $\mathbf{c}_1, \mathbf{c}_2, \dots, \mathbf{c}_K$ of Equation (32) are given by Equations (24) and (25) for $k = 1, 2, \dots, K$.*

Proof. The proof of Corollary 1 holds in the general case, since the minimizers are calculated separately.

The Weiszfeld Method

In the case of one cluster (where the probabilities are all 1 and therefore of no interest), the center formulas (24) and (25) reduce to

$$\mathbf{c} = \sum_{i=1, \dots, N} \left(\frac{1/d(\mathbf{x}_i, \mathbf{c})}{\sum_{j=1, \dots, N} 1/d(\mathbf{x}_j, \mathbf{c})} \right) \mathbf{x}_i, \quad (33)$$

giving the minimizer of $f(\mathbf{c}) = \sum_{i=1}^N d(\mathbf{x}_i, \mathbf{c})$. Formula (33) can be used iteratively to update the center $\mathbf{c}$ (on the left) as a convex combination of the points $\mathbf{x}_i$ with weights depending on the current center. This iteration is the *Weiszfeld method* [29] for solving the Fermat–Weber location problem, see Refs 29 and 30. Convergence

of Weiszfeld's method was established in Kuhn [23] by modifying the gradient $\nabla f(\mathbf{c})$ so that it is always defined, see Ref. 31 for further details. However, the modification is not carried out in practice since, as shown by Kuhn, the set of initial points $\mathbf{c}$ for which it ever becomes necessary is denumerable.

In what follows, we use the formulas (24) and (25) iteratively to update the centers. Convergence can be proved by adapting the arguments of Kuhn [23], but as before, it requires no special steps in practice.

The Centers and The Joint Distance Function

The centers given by Equations (24) and (25) are related to the JDF (Eq. 13) of the data set. Consider first the case of $K = 2$ clusters, where (Eq. 13) reduces to

$$F(\mathbf{c}_1, \mathbf{c}_2) = \sum_{i=1}^N \frac{d_1(\mathbf{x}_i, \mathbf{c}_1) d_2(\mathbf{x}_i, \mathbf{c}_2)}{d_1(\mathbf{x}_i, \mathbf{c}_1) + d_2(\mathbf{x}_i, \mathbf{c}_2)}. \quad (34)$$

The points $\mathbf{c}_k$ where $\nabla_{\mathbf{c}_k} F(\mathbf{c}_1, \mathbf{c}_2) = \mathbf{0}$, $k = 1, 2$, are called *stationary points* of Equation (34).

Theorem 3. *Let the distances d_1, d_2 in Equation (34) be elliptic, as in Equation (30). Then the stationary points of $F(\mathbf{c}_1, \mathbf{c}_2)$ are given by Equations (24)–(26).*

Proof. Let the distances d_k be Euclidean, $d_k(\mathbf{x}) = \|\mathbf{x} - \mathbf{c}_k\|$. It is enough to prove the theorem for one center, say $\mathbf{c}_1$. Using Equation (27) we derive

$$\begin{aligned} \nabla_{\mathbf{c}_1} F(\mathbf{c}_1, \mathbf{c}_2) &= \sum_{i=1}^N \frac{(d_1(\mathbf{x}_i) + d_2(\mathbf{x}_i)) d_2(\mathbf{x}_i) \left(-\frac{\mathbf{x}_i - \mathbf{c}_1}{d_1(\mathbf{x}_i)} \right) + d_1(\mathbf{x}_i) d_2(\mathbf{x}_i) \left(\frac{\mathbf{x}_i - \mathbf{c}_1}{d_1(\mathbf{x}_i)} \right)}{(d_1(\mathbf{x}_i) + d_2(\mathbf{x}_i))^2} \\ &= \sum_{i=1}^N \frac{-d_2(\mathbf{x}_i)^2 (\mathbf{x}_i - \mathbf{c}_1)}{d_1(\mathbf{x}_i) (d_1(\mathbf{x}_i) + d_2(\mathbf{x}_i))^2}. \end{aligned} \quad (35)$$

Setting Equation (35) equal to zero, and summing like terms, we get

$$\begin{aligned} &\left(\sum_{j=1}^N \frac{d_2(\mathbf{x}_j)^2}{d_1(\mathbf{x}_j) (d_1(\mathbf{x}_j) + d_2(\mathbf{x}_j))^2} \right) \mathbf{c}_1 \\ &= \sum_{i=1}^N \left(\frac{d_2(\mathbf{x}_i)^2}{d_1(\mathbf{x}_i) (d_1(\mathbf{x}_i) + d_2(\mathbf{x}_i))^2} \right) \mathbf{x}_i, \end{aligned}$$

duplicating Equations (24)–(26). If the distances are elliptic, as in Equation (30), then the analog of Equation (35) is

$$\nabla_{\mathbf{c}_1} F(\mathbf{c}_1, \mathbf{c}_2) = \sum_{i=1}^N \frac{-d_2(\mathbf{x}_i)^2 Q_1(\mathbf{x}_i - \mathbf{c}_1)}{d_1(\mathbf{x}_i) (d_1(\mathbf{x}_i) + d_2(\mathbf{x}_i))^2},$$

and since Q_1 is nonsingular, it can be “cancelled” when the gradient is set equal to zero.

In the above proof, the stationary points $\mathbf{c}_1, \mathbf{c}_2$ are calculated separately, and the calculation does not depend on there being 2 clusters. We thus have the following corollary.

Corollary 3. *Consider a data set with K clusters, and elliptic distances d_k . Then the stationary points of the JDF (Eq. 13) are the centers $\mathbf{c}_k$ given by Equations (24) and (25).*

Note: The JDF (10) is zero exactly at the K centers $\{\mathbf{c}_k\}$, and is positive elsewhere. These centers are therefore the global minimizers of Equation (10). However, the function (Eq. 10) is not convex, not even quasi-convex, and may have other stationary points that are necessarily saddle points.

Why d and Not d^2 ?

The extremal principle (Eq. 18), which is the basis of our work, is linear in the distances d_k ,

$$\text{Minimize} \quad \sum_k d_k p_k^2.$$

We refer to this as the *d-model*.

In clustering, and statistics in general, it is customary to use the distances squared in the objective function,

$$\text{Minimize} \quad \sum_k d_k^2.$$

We call this the d^2 -model.

The d^2 -model has a long tradition, dating back to Gauss, and is endowed with a rich statistical theory. There are geometrical advantages (Pythagoras Theorem), as well as analytical (linear derivatives).

The d -model is suggested by the analogy between clustering and location problems, where sums of distances (not distances squared) are minimized. Our center formulas (Eqs 24 and 25) are thus generalizations of the Weiszfeld method to several facilities.

An advantage of the d -model is its robustness. Indeed formula (25), which does not follow from the d^2 -model, guarantees that outliers will not affect the center locations.

Other Principles

There are alternative ways of modeling the relations between distances and probabilities. For example:

Principle 2. For each $\mathbf{x} \in \mathcal{D}$, and each cluster C_k , the probability $p_k = p_k(\mathbf{x})$ and distance $d_k = d_k(\mathbf{x})$ are related by

$$p_k^\alpha d_k^\beta = \text{constant, depending on } \mathbf{x}, \quad (36)$$

where the exponents α, β are positive.

For the case of two clusters we get, by analogy with Equations (8) and (18) respectively, the probabilities

$$\begin{aligned} p_1(\mathbf{x}) &= \frac{d_2(\mathbf{x})^{\beta/\alpha}}{d_1(\mathbf{x})^{\beta/\alpha} + d_2(\mathbf{x})^{\beta/\alpha}}, \\ p_2(\mathbf{x}) &= \frac{d_1(\mathbf{x})^{\beta/\alpha}}{d_1(\mathbf{x})^{\beta/\alpha} + d_2(\mathbf{x})^{\beta/\alpha}}, \end{aligned} \quad (37)$$

and an extremal principle,

$$\begin{aligned} \text{Minimize} \quad & \sum_{i=1}^N \left(d_1(\mathbf{x}_i)^\beta p_1(i)^{\alpha+1} + d_2(\mathbf{x}_i)^\beta p_2(i)^{\alpha+1} \right) \\ \text{subject to} \quad & p_1(i) + p_2(i) = 1 \\ & p_1(i), p_2(i) \geq 0, \end{aligned} \quad (38)$$

where $p_1(i), p_2(i)$ are the cluster probabilities at $\mathbf{x}_i$.

The *Fuzzy Clustering Method* [16,32], which is an extension of k -means method, uses $\beta = 2$ and allows different choices of α . For $\alpha = 2$, it gives the same probabilities as Equation (7), however the center updates are different from Equations (24) and (25).

PROBABILISTIC EXPONENTIAL D-CLUSTERING

Any increasing function of the distance can be used in Principle 1. The following model, with probabilities decaying exponentially as distances increase, has proved useful in our experience.

Principle 3. For each $\mathbf{x} \in \mathcal{D}$, and each cluster C_k , the probability $p_k(\mathbf{x})$ and distance $d_k(\mathbf{x})$ are related by

$$p_k(\mathbf{x}) e^{d_k(\mathbf{x})} = E(\mathbf{x}), \text{ a constant depending on } \mathbf{x}. \quad (39)$$

Most results of the section titled Probabilistic D-Clustering also hold for Principle 3, with the distance $d_k(\mathbf{x})$ replaced by $e^{d_k(\mathbf{x})}$. Thus the analog of the probabilities (Eq. 8) is

$$\begin{aligned} p_1(\mathbf{x}) &= \frac{e^{d_2(\mathbf{x})}}{e^{d_1(\mathbf{x})} + e^{d_2(\mathbf{x})}}, \\ p_2(\mathbf{x}) &= \frac{e^{d_1(\mathbf{x})}}{e^{d_1(\mathbf{x})} + e^{d_2(\mathbf{x})}}, \end{aligned} \quad (40)$$

or equivalently

$$\begin{aligned} p_1(\mathbf{x}) &= \frac{e^{-d_1(\mathbf{x})}}{e^{-d_1(\mathbf{x})} + e^{-d_2(\mathbf{x})}}, \\ p_2(\mathbf{x}) &= \frac{e^{-d_2(\mathbf{x})}}{e^{-d_1(\mathbf{x})} + e^{-d_2(\mathbf{x})}}. \end{aligned} \quad (41)$$

Similarly, since the probabilities add to 1, the constant in Equation (39) is

$$E(\mathbf{x}) = \frac{e^{d_1(\mathbf{x})+d_2(\mathbf{x})}}{e^{d_1(\mathbf{x})} + e^{d_2(\mathbf{x})}}, \quad (42)$$

also called the *exponential JDF*.

An Extremal Principle

The probabilities (Eq. 40) are the optimal solutions of the problem

$$\min_{p_1, p_2} \left\{ e^{d_1} p_1^2 + e^{d_2} p_2^2 : p_1 + p_2 = 1, \right. \\ \left. p_1, p_2 \geq 0 \right\}, \quad (43)$$

whose optimal value, obtained by substituting the probabilities (Eq. 40), is again the exponential JDF of Equation (42).

The extremal problem for a data set $\mathcal{D} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N\} \subset \mathbb{R}^n$, partitioned into two clusters, is the following analog of Equation (18):

$$\text{Minimize } \sum_{i=1}^N \left(e^{d_1(\mathbf{x}_i)} p_1(i)^2 + e^{d_2(\mathbf{x}_i)} p_2(i)^2 \right) \\ \text{subject to } p_1(i) + p_2(i) = 1 \\ p_1(i), p_2(i) \geq 0, \quad (44)$$

where $p_1(i), p_2(i)$ are the cluster probabilities at $\mathbf{x}_i$. The problem separates into N problems like Equation (43), and its optimal value is

$$\sum_{i=1}^N \frac{e^{d_1(\mathbf{x}_i) + d_2(\mathbf{x}_i)}}{e^{d_1(\mathbf{x}_i)} + e^{d_2(\mathbf{x}_i)}}, \quad (45)$$

the exponential JDF of the whole data set.

Alternatively, Equation (39) follows from the “smoothed” extremal principle

$$\min_{p_1, p_2} \left\{ \sum_{k=1}^2 p_k d_k + \sum_{k=1}^2 p_k \log p_k \right. \\ \left. : p_1 + p_2 = 1, p_1, p_2 \geq 0 \right\}, \quad (46)$$

obtained by adding an entropy term to $\sum p_k d_k$. Indeed the Lagrangian of Equation (46) is

$$L(p_1, p_2, \lambda) = \sum_{k=1}^2 p_k d_k + \sum_{k=1}^2 p_k \log p_k \\ - \lambda (p_1 + p_2 - 1).$$

Differentiation with respect to p_k , and equating to 0, gives

$$d_k + 1 + \log p_k - \lambda = 0,$$

which is Equation (39).

Centers

We write Equation (44) as a function of the cluster centers $\mathbf{c}_1, \mathbf{c}_2$,

$$f(\mathbf{c}_1, \mathbf{c}_2) \\ = \sum_{i=1}^N \left(e^{d_1(\mathbf{x}_i, \mathbf{c}_1)} p_1(\mathbf{x}_i)^2 + e^{d_2(\mathbf{x}_i, \mathbf{c}_2)} p_2(\mathbf{x}_i)^2 \right), \quad (47)$$

and for elliptic distances we can verify, as in Theorem 2, that the minimizers of Equation (47) are given by

$$\mathbf{c}_k = \sum_{i=1}^N \left(\frac{u_k(\mathbf{x}_i)}{\sum_{j=1}^N u_k(\mathbf{x}_j)} \right) \mathbf{x}_i, \quad (48)$$

where [compare with Equation (25)],

$$u_k(\mathbf{x}_i) = \frac{p_k(\mathbf{x}_i)^2 e^{d_k(\mathbf{x}_i)}}{d_k(\mathbf{x}_i)}, \quad (49)$$

or equivalently,

$$u_1(\mathbf{x}_i) = \frac{e^{-d_1(\mathbf{x}_i)}/d_1(\mathbf{x}_i)}{(e^{-d_1(\mathbf{x}_i)} + e^{-d_2(\mathbf{x}_i)})^2}, \\ u_2(\mathbf{x}_i) = \frac{e^{-d_2(\mathbf{x}_i)}/d_2(\mathbf{x}_i)}{(e^{-d_1(\mathbf{x}_i)} + e^{-d_2(\mathbf{x}_i)})^2}. \quad (50)$$

As in Theorem 3, these minimizers are the stationary points of the JDF, given here as

$$F(\mathbf{c}_1, \mathbf{c}_2) = \sum_{i=1}^N \frac{e^{d_1(\mathbf{x}_i, \mathbf{c}_1) + d_2(\mathbf{x}_i, \mathbf{c}_2)}}{e^{d_1(\mathbf{x}_i, \mathbf{c}_1)} + e^{d_2(\mathbf{x}_i, \mathbf{c}_2)}}. \quad (51)$$

Finally we can verify, as in Corollary 2, that the results hold in the general case of K clusters.

Figure 3. Flowchart of the probabilistic distance clustering algorithm.

A PROBABILISTIC D-CLUSTERING ALGORITHM

The ideas in the sections titled “*Probabilistic D-Clustering*” and “*Probabilistic Exponential D-Clustering*” are implemented in the

following algorithm for unsupervised clustering of data (Fig. 3). Steps of the algorithm are explained in detailed below and Algorithm 1 presents those steps—for simplicity—for the case of two clusters.

Algorithm 1. Steps of a probabilistic d-clustering algorithm

Initialization: given data $\mathcal{D}$, any two points $\mathbf{c}_1, \mathbf{c}_2$, and $\epsilon > 0$

Iteration:

Step 1 **compute** distances $d_1(\mathbf{x}), d_2(\mathbf{x})$ for all $\mathbf{x} \in \mathcal{D}$
 Step 2 **update** the centers $\mathbf{c}_1^+, \mathbf{c}_2^+$
 Step 3 **if** $\|\mathbf{c}_1^+ - \mathbf{c}_1\| + \|\mathbf{c}_2^+ - \mathbf{c}_2\| < \epsilon$ **stop**
 return to step 1

The algorithm starts with random initial centers (number of clusters are given by the user). In *Step-1*, the distances of the data points to each center are computed. In *Step-2*, the centers are updated with the distances computed in Step-1 using Equations (24) or (48). The algorithm iterates between the cluster centers and the distances of the data points to these centers. The computations stop (in *Step 3*) when the centers stop moving.

The distance used in *Step 1* can be Euclidean or elliptic (the formulas 24–26, and 48–50, are valid in both cases). In *Step 2*, the centers are updated by Equations (24)–(26) if Principle 1 is used, and by Equations (48)–(50) for Principle 3. In particular, if the Mahalanobis distance (Eq. 14)

$$d(\mathbf{x}, \mathbf{c}_k) = \sqrt{(\mathbf{x} - \mathbf{c}_k)^T \Sigma_k^{-1} (\mathbf{x} - \mathbf{c}_k)}$$

Figure 4. The level sets of the evolving *joint distance function* at (a) iteration 0, (b) iteration 2, (c) iteration 5, and (d) iteration 14.

is used, the covariance matrix Σ_k of the k th-cluster, can be estimated at each iteration by

$$\Sigma_k = \frac{\sum_{i=1}^N u_k(\mathbf{x}_i)(\mathbf{x}_i - \mathbf{c}_k)(\mathbf{x}_i - \mathbf{c}_k)^T}{\sum_{i=1}^N u_k(\mathbf{x}_i)}, \quad (52)$$

with $u_k(\mathbf{x}_i)$ given by Equation (26) or Equation (50).

The cluster membership *probabilities* of the data points are not used explicitly in the algorithm. When the computations stop in (Step-3), the cluster membership probabilities can be computed by Equation (8) or Equation (40). These probabilities are not needed in the algorithm but they can be used

for classifying the data points after computing the cluster centers.

Using the arguments of Ref. 23, it can be shown that the objective function (Eq. 32) decreases at each iteration, and the algorithm converges. The cluster centers and distance functions change at each iteration, and so does the *JDF function* (Eq. 13) itself, which decreases at each iteration. The JDF may have stationary points that are not minimizers, however such points are necessarily saddle points and will be missed by the algorithm with probability 1.

Example 3. We apply *Algorithm 1*, using Mahalanobis distance, to the data of Example 1. Figure 4 shows the evolution of the JDF, represented by its level sets.

Figure 5. Movements of the cluster centers for different starts. (a) shows the centers corresponding to Fig. 4. (b) shows very close initial centers.

The initial function, shown in Fig. 5a, corresponds to the (arbitrarily chosen) initial centers and initial covariances $\Sigma_1 = \Sigma_2 = I$. The covariances are updated at each iteration using Equation (52), and by iteration 8 the function is already very close to its final form, as shown in Fig. 5d. For a tolerance of $\epsilon = 0.01$, the algorithm terminated in 12 iterations.

Example 4. In Fig. 5 we illustrate the movement of the cluster centers for different initial centers. The centers at each run are shown with the final level sets of the JDF found in Example 3.

The algorithm gives the correct cluster centers, for all initial starts. In particular,

the two initial centers may be arbitrarily close, as shown in Fig. 5b.

Example 5. The class membership probabilities (Eq. 8) were then computed using the centers determined by the algorithm. The level sets of the probability $p_1(\mathbf{x})$ are shown in Fig. 6. The curve $p_1(\mathbf{x}) = 0.5$, the thick curve shown in Fig. 6a, may serve as the clustering rule. Alternatively, the two clusters can be defined as

$$C_1 = \{\mathbf{x} : p_1(\mathbf{x}) \geq 0.6\}, C_2 = \{\mathbf{x} : p_1(\mathbf{x}) \leq 0.4\},$$

with points $\{\mathbf{x} : 0.4 < p_1(\mathbf{x}) < 0.6\}$ left unclassified, as in Fig. 6b.

Figure 6. The level sets of the probabilities $p_1(\mathbf{x})$ and two clustering rules.

THE CLASSIFICATION UNCERTAINTY FUNCTION

The JDF has the dimension of distance. Normalizing it, we get the dimensionless function

$$U(\mathbf{x}) = K D(\mathbf{x}) / \left(\prod_{j=1}^K d_j(\mathbf{x}) \right)^{1/K}, \quad (53)$$

with $0/0$ interpreted as zero. Using Equations (7) and (10), $U(\mathbf{x})$ can be written as the geometric mean of the probabilities (up

to a constant)

$$U(\mathbf{x}) = K \left(\prod_{j=1}^K p_j(\mathbf{x}) \right)^{1/K}. \quad (54)$$

In particular, for $K = 2$,

$$U(\mathbf{x}) = 2 \frac{\sqrt{d_1(\mathbf{x})d_2(\mathbf{x})}}{d_1(\mathbf{x}) + d_2(\mathbf{x})} = 2\sqrt{p_1(\mathbf{x})p_2(\mathbf{x})}. \quad (55)$$

The function $U(\mathbf{x})$ in Equation (53) is the harmonic mean of the distances $\{d_j(\mathbf{x})\}$ divided by their geometric mean. It follows

Figure 7. Illustration of Example 1: the decrease of classification uncertainty.

Figure 8. The level sets of the evolving classification uncertainty function at (a) iteration 0, (b) iteration 2, (c) iteration 3, and (d) iteration 14.

that $0 \leq U(\mathbf{x}) \leq 1$, with $U(\mathbf{x}) = 0$ if any $d_j(\mathbf{x}) = 0$, that is if $\mathbf{x}$ is a cluster center, and $U(\mathbf{x}) = 1$ if and only if the probabilities $p_j(\mathbf{x})$ are all equal. The values of $U(\mathbf{x})$ thus indicate the uncertainty of classifying the point $\mathbf{x}$ to one of the clusters. We call $U(\mathbf{x})$ the *classification uncertainty function*, abbreviated *CUF*, at $\mathbf{x}$. See Ref. 9 for a discussion of the CUF, and a justification for interpreting it as an entropic measure of uncertainty.

The CUF of the data set $\mathcal{D} = \{\mathbf{x}_i : i \in \overline{1, N}\} = \mathcal{C}_1 \cup \mathcal{C}_2 \cup \dots \cup \mathcal{C}_K$ with K clusters is

defined as

$$U_K(\mathcal{D}) := \frac{1}{N} \sum_{i=1}^N U(\mathbf{x}_i). \quad (56)$$

By definition, $U_1(\mathcal{D}) = 1$ since all probabilities are trivially 1 if there is just one cluster. At the other extreme, if every point is a separate cluster, it then has a zero probability of belonging to the other clusters, and therefore $U_N(\mathcal{D}) = 0$.

The classification uncertainty of the data set, measured by the CUF of the data set in Example 1, decreases at each iteration, converging to a residual uncertainty of about 0.7 (Fig. 7). This decrease is illustrated in Fig. 8, showing the level sets of the CUF

Figure 9. Results for Example 6.(a) A data set with $K = 2$ clusters and (b)the CUF as a function of K .

in Equation (54), with data points gradually “moving” into the level sets of lower uncertainty.

CLUSTERING VALIDATION

An important issue in clustering is to determine the “right” number K of clusters that fits a given data set with N points. In dichotomous situations the answer $K = 2$ is obvious, but in General, the answer lies between the two extremes of $K = 1$ (one cluster fits all), and $K = N$ (each point is a cluster). The CUF

of the data set, $U_K(\mathcal{D})$ given in Equation (56), helps resolve this issue [39].

Indeed, the value of $U_K(\mathcal{D})$ decreases monotonically with K , from $U_1(\mathcal{D}) = 1$ down to $U_N(\mathcal{D}) = 0$. The decrease of the uncertainty $U_K(\mathcal{D})$ is precipitous until the “right” K is reached, and after that the graph is almost flat. This suggests clustering the data set in question into $K = 1, 2, 3, \dots$ clusters, stopping at a value of K where the rate of decrease of $U_K(\mathcal{D})$ drops below a certain tolerance.

Figure 10. Note the change of slope of the CUF at $K = 3$. (a) A data set with $K = 3$ clusters and (b) the CUF as a function of K .

Figure 11. The slope of the CUF changes continuously. (a) A data set with no structure and (b) the CUF as a function of K .

This approach is practical because the d -clustering algorithm is fast, and it generates the information needed for computing the criterion (the value of the CUF), unlike other approaches that require external criteria. See also the survey in Ref. 33.

Example 6. Figure 9a shows a data set with two clusters. The d -clustering algorithm was applied to this data set, and the values of the $U_K(\mathcal{D})$ were computed for K from 1 to 10, the results are plotted in Fig. 9b. Note the drop from $U_1(\mathcal{D}) = 1$ to $U_2(\mathcal{D}) = 0.55$, and the change of slope at $K = 2$.

Figure 10a similarly shows a data set with $K = 3$ clusters. The CUF is plotted in Fig. 10b, revealing the correct number of clusters. Indeed, $U_K(\mathcal{D})$ drops from $U_2(\mathcal{D}) = 0.66$ to $U_3(\mathcal{D}) = 0.47$, and the rate of decrease is much smaller for $K > 3$.

If there is no clear answer for the number of clusters, as in Fig. 11a, then the CUF does not give an answer (Fig. 11b).

RELATED WORK

The data is given as a similarity matrix in many applications. For the analysis of such data using probabilistic distance clustering, see Ref. 34.

There are applications where the *cluster sizes* (ignored here) need to be estimated.

An important example is parameter estimation in mixtures of distributions. The above method, adjusted for cluster sizes, is applicable, and in particular presents a viable alternative to the Expectation-Maximization (EM) method, see Refs 35 and 36.

Our method allows an extension of the classical Weiszfeld method to several facilities. This is the subject of Ref. 37, giving the solution of *multifacility location problems*, including the capacitated case (which corresponds to given cluster sizes).

Semisupervised clustering is a framework for reconciling *supervised learning*, using any prior information (“labels”) on the data, with *unsupervised clustering*, based on the intrinsic properties and geometry of the data set. A new method for semisupervised clustering, combining probabilistic distance clustering for the unlabeled data points and a least squares criterion for the labeled ones, is given in Ref. 9.

PROBABILITY WEIGHTING FUNCTIONS

ALI AL-NOWAIHI
SANJIT DHAMI
Department of Economics,
University of Leicester,
Leicester, UK

Under expected utility (EU) theory, decision makers weight probabilities linearly. But the evidence strongly suggests nonlinear weighting of probabilities. Consider the following example from Kahneman and Tversky [[1], p. 283]. Suppose that one is compelled to play Russian roulette. One would be willing to pay much more to reduce the number of bullets from one to zero than from four to three. However, in each case, the reduction in the probability of a bullet firing is 1/6, and so, under EU, the decision maker should be willing to pay the same amount. This suggests nonlinear weighting of probabilities, which is also supported by the emerging neuroeconomic evidence [2].

The main alternatives to EU—*rank-dependent utility* (RDU), *prospect theory* (PT), and *cumulative prospect* (CP) *theory*—incorporate nonlinear weighting of probabilities using the device of a *probability weighting function* (PWF). Sections titled “Foundations and Principles of Decision Analysis,” “Psychological Basis of Decision-making under Uncertainty and Risk,” “Normative Structuring of Decision Problems,” “Modeling a Decision Maker’s Preferences for Outcomes,” and “Modeling a Decision Maker’s Risk Attitude” of this encyclopedia and, in particular, the five articles in the section titled “Foundations and Principles of Decision Analysis” discuss the axiomatic foundations of EU, RDU, PT, and CP. They discuss the nonparametric restrictions that must be imposed on the PWF. The main restrictions are that the PWF is a continuous, increasing function. This, for instance, is the case in the axiomatizations of RDU by Abdellaoui [3] and Wakker [4].

By contrast, the aim of this article is to explore the parametric PWFs. Our approach, therefore, complements the material elsewhere in the Encyclopedia, gives concrete guidance to the use of PWFs in practical applications, and imposes parametric restrictions on the PWF, which allows for sharper tests of the predictions.

SOME BASICS

Let $X = \{x_1, x_2, \dots, x_n\}$ be a fixed finite set of real numbers, which represents the possible monetary *outcomes/wealth levels*. Assume that $x_1 < x_2 < \dots < x_n$. The decision maker has a set of feasible actions, A . Any action in A induces a probability distribution $(p_1, p_2, \dots, p_n)$, $p_i \geq 0$ and $\sum_{i=1}^n p_i = 1$, over the outcomes. We then define a *first-order lottery*, L , as

$$L = (x_1, p_1; x_2, p_2; \dots; x_n, p_n), \quad (1)$$

with the interpretation that outcome x_i occurs with probability p_i . Higher order lotteries (lotteries of lotteries) can then be defined by recursion. Let $\mathcal{L}$ be the set of all lotteries. How should the decision maker choose an action in A ? Expected utility (EU) theory postulates that a decision maker has a complete transitive preference ordering, $\preceq$, on $\mathcal{L}$. Under well-known assumptions [5] each lottery is equivalent (under $\preceq$) to a first-order lottery. Furthermore, $\preceq$ can be represented by an expected utility functional, $EU : \mathcal{L} \rightarrow \mathbb{R}$, which takes the form

$$EU(L) = \sum_{i=1}^n p_i u(x_i), \quad (2)$$

where $u(x_i)$ is the utility of the outcome x_i and $(x_1, p_1; x_2, p_2; \dots; x_n, p_n)$ is the first-order lottery equivalent to L . Thus, $L_1 \preceq L_2 \Leftrightarrow EU(L_1) \leq EU(L_2)$. A key axiom used in the derivation of Equation (2) is the *independence axiom*.

Definition 1. [Independence axiom].

Suppose that $\preceq$ is a preference relation defined over the set of lotteries. Then for all lotteries L_1, L_2, L , and all $p \in [0, 1]$, $L_1 \preceq L_2 \Leftrightarrow (L_1, p; L, 1-p) \preceq (L_2, p; L, 1-p)$.

The independence axiom is often violated by the evidence. Alternatives to EU mainly relax this axiom. Two main features of EU stand out. (i) There is additive separability across outcomes. (ii) The objective function is linear in probabilities. Most alternatives to EU relax the second feature, that is, linearity in probabilities.

Suppose that the decision maker weights outcome x_i with the weight π_i . Suppose that in place of Equation (2) we have

$$V(L) = \sum_{i=1}^n \pi_i u(x_i). \quad (3)$$

Clearly, Equation (2) is the special case of Equation (3) with $\pi_i = p_i$. Early generalizations of EU took π_i to be a function of p_i . However, it is well known that such a point transformation of objective probabilities can lead the decision maker to choose stochastically dominated options (violation of monotonicity) even when such dominance is obvious [6].

STYLIZED FACTS ON NONLINEAR WEIGHTING OF PROBABILITIES

On the basis of brief discussion so far, we summarize two stylized facts, S1 and S2.

- S1. Evidence suggests that decision makers weight probabilities in a nonlinear manner. In particular, the evidence suggests that decision makers overweight low probabilities and underweight high probabilities (inverse S-shaped probability weighting).
- S2. Nonlinear point transformation of probabilities, $\pi_i = \pi_i(p_i)$, can violate monotonicity even when such violation is obvious.

A third stylized fact of at least equal significance but that has received relatively less attention in theoretical work is the following.

- S3. For events close to the boundary of the probability interval, $[0, 1]$, extensive empirical evidence suggests that decision makers (i) ignore events of extremely low probability and (ii) treat extremely high probability events as certain. In contrast to S1, S3 applies only to very low and very high probabilities.

We emphasize that we are not making a case for ditching S1. Indeed S1 is a robust empirical finding that allows one to resolve many important problems and puzzles in the literature. However, S1, in the absence of S3, leads to severe problems for theory in explaining facts concerning events with probabilities close to the end points of the probability interval $[0, 1]$. Indeed al-Nowaihi and Dhami [7–9] show that the set of such problems is large and economically important. Hence, we make the case for a class of probability weighting functions that simultaneously incorporates both S1 and S3. Furthermore, our own view is that one cannot argue that either S1 or S3 is more important than the other.

S1 and S2 are well documented; see Starmer [6] and Kahneman and Tversky [10], and Appendix A in Wakker [11]. However, S3 is less well documented, and theoretical work that incorporates it explicitly and formally has only just begun to appear. We now briefly review the evidence for S3.

EVIDENCE FOR S3

In their Nobel prize winning work on *prospect theory* (PT), Kahneman and Tversky [1] were acutely aware of S3 and they explicitly chose to emphasize it's salience. In PT, there is a psychologically rich *editing* phase followed by an *evaluation/decision* phase; the latter uses a rule of the form (3). From our perspective, the most critical aspect of the editing phase arises when decision makers decide which extreme probability events to ignore. This is reflected in the manner that $\pi(p)$ is drawn by Kahneman and Tversky [1] (Fig. 1).

Kahneman and Tversky [1] wrote the following (pp. 282–283) to cogently summarize the evidence on the end points of the probability interval $[0, 1]$: *The sharp drops or*

Figure 1. Ignorance at the end points.
[Source: Kahneman and Tversky [1, p. 283]].

apparent discontinuities of $\pi(p)$ at the end points are consistent with the notion that there is a limit to how small a decision weight can be attached to an event, if it is given any weight at all. A similar quantum of doubt could impose an upper limit on any decision weight that is less than unity... On the other hand, the simplification of prospects can lead the individual to discard events of extremely low probability and to treat events of extremely high probability as if they were certain. Because people are limited in their ability to comprehend and evaluate extreme probabilities, highly unlikely events are either ignored or overweighted, and the difference between high probability and certainty is either neglected or exaggerated. Consequently $\pi(p)$ is not well-behaved near the end points.

Dharm and al-Nowaihi [7–9]) review evidence strongly supportive of the claim of Kahneman and Tversky [1], from many disparate contexts. We now draw on these papers to briefly, and selectively, summarize the evidence.

Remark 1. Just so as to be absolutely clear we are not arguing that stylized fact S3 applies to all individuals. However, depending on the context, we argue that it could apply to a sizable number of people. Our model is capable of incorporating both sets of individuals: those to whom S3 applies and those to whom it does not. Indeed there is a well-developed notion of *bimodal perception of risks* in psychology that we outline in the

section titled “A Possible Formalization of the Bimodal Perception of Risk”. In this notion, some individuals are concerned mainly with the size of a loss while others, to whom stylized fact S3 applies, are mainly concerned about the probability. For the latter set of individuals, attention to losses declines dramatically as the probability falls below a minimum threshold. Theory needs to be able to accommodate both sets of individuals; we show that this is true of our theory in the section titled “A Possible Formalization of the Bimodal Perception of Risk”

Insurance for Low Probability Events

The insurance industry is of tremendous economic importance. Yet, despite impressive progress, existing theoretical models are unable to explain the stylized facts on the take-up of insurance for low probability events. The seminal study by Kunreuther *et al.* [12] provides striking evidence of individuals buying inadequate, nonmandatory, insurance against low probability events (e.g., earthquake, flood, and hurricane damage in areas prone to these hazards).

EU predicts that a risk-averse decision maker facing an actuarially fair premium will, in the absence of transaction costs, buy *full* insurance for all probabilities, however small. To test this prediction, Kunreuther *et al.* [[12], Chapter 7] presented subjects with varying potential losses with various probabilities, keeping the expected value of

the loss constant. Subjects faced actuarially fair, unfair, or subsidized premiums. In each case, they found that there is a point below which the take-up of insurance drops dramatically, as the probability of the loss decreases (and as the magnitude of the loss increases, keeping the expected loss constant). These results were shown to be robust to a very large number of perturbations and factors that include generous government incentives to reduce premiums to below market rates, controlling for moral hazard, and so on; see al-Nowaihi and Dhami [8] for details.

Arrow's own reading of the evidence in Kunreuther *et al.* [12], summarized in the foreword to Kunreuther *et al.* [12], is that: *Obviously in some sense it is right that he or she [the insuree] be less aware of low probability events, other things being equal; but it does appear from the data that the sensitivity goes down too rapidly as the probability decreases.*

Kunreuther *et al.* [12] write: *Based on these results, we hypothesize that most homeowners in hazard-prone areas have not even considered how they would recover should they suffer flood or earthquake damage. Rather they treat such events as having a probability of occurrence sufficiently low to permit them to ignore the consequences* These results are borne out from further testing by Camerer and Kunreuther [13] who conclude that: *Individuals seem to buy insurance only when the probability of risk is above a threshold . . .* This behavior is in close conformity to the observations of Kahneman and Tversky [1] outlined above.

The Becker Paradox

A celebrated result of Becker [14], which is known as the Becker proposition states that the most efficient way to deter a crime is to impose the *severest possible penalty with the lowest possible probability*. By reducing the probability of detection and conviction, society can economize on the costs of enforcement such as policing and trial costs. But by increasing the severity of the punishment (e.g., fines) the deterrence effect of the punishment is maintained. Indeed, under EU,

risk neutrality or risk aversion, and allowing for infinitely severe punishments, the Becker proposition implies that crime would be deterred completely, however small the probability of detection and conviction. Risk seeking behavior is not sufficient to overturn the Becker proposition either [9]. The Becker proposition is sometimes phrased as *it is efficient to hang offenders with probability zero*. Empirical evidence, summarized in Dhami and al-Nowaihi [9], however, is not supportive of the Becker proposition. This, we call as the Becker paradox.

Remark 2. It is shown in Dhami and al-Nowaihi [9], in detail, that nine explanations that have been seriously proposed in the literature cannot explain the Becker paradox. These explanations include the following: risk seeking behavior on the part of offenders, the ability to avoid severe fines by declaring bankruptcy, the need for differential punishments, type-I and type-II errors in conviction, rent seeking behavior in the presence of severe punishments, abhorrence of severe punishments, objectives other than deterrence, non-availability of severe punishments, and the psychological traits of offenders.

The behavior of decision makers for low probability events is critical to understanding the Becker paradox. Dhami and al-Nowaihi [9] show that if the probability weighting function respects stylized fact S1 but not S3, then the Becker paradox survives even under RDU and CP. However, once one allows for a probability weighting function that respects both stylized facts S1 and S3, then in conjunction with the reference point feature of CP, Dhami and al-Nowaihi [9] show that the Becker paradox is easily resolved. Indeed, S3 turns out to be a necessary condition for the resolution of the Becker paradox (and related paradoxes, see Remark 3).

Remark 3. The Becker paradox is a general paradox that applies to all situations where a decision maker is *not* deterred from some act, a , that would result in *almost infinite punishment with small probability*. In each

of these cases, and under plausible assumptions on risk attitudes, EU predicts that the decision maker will be *dissuaded* from the act a . Under RDU and CP the standard probability weighting functions respect S1 but not S3. This acts to dissuade the decision maker even more powerfully from the act a , as compared to EU. Hence, as al-Nowaihi and Dhami [7–9] show formally, standard theories with nonlinear weights make the Becker paradox even worse. Furthermore, they show that the simultaneous incorporation of S1 and S3 into the same probability weighting function is a necessary condition for solving the class of Becker paradoxes. In the remaining part of this section we consider more examples of the Becker paradox. These include evidence from jumping red traffic lights, driving and talking on mobile phones, seat belt usage, and the take-up of breast cancer examinations.

Evidence from Jumping Red Traffic Lights

In running red lights there is a *small probability* of an accident. However, the consequences are self-inflicted and potentially have *infinite costs*. This act is, therefore, like the act a in Remark 3. Rephrased, running red traffic lights is similar to *hanging oneself with a very small probability*, which is similar to the Becker proposition.

It is estimated in Bar Ilan and Sacerdote [15] that there are approximately 260,000 accidents per year in the United States caused by red-light running with implied costs of car repair alone of the order of \$520 million per year. Using Israeli data, the authors [16] calculated that the expected gain from jumping one red traffic is, at most, 1 min (the length of a typical light cycle). Given the known probabilities, they find that: *If a slight injury causes a loss greater or equal to 0.9 days, a risk neutral person will be deterred by that risk alone. However, the corresponding numbers for the additional risks of serious and fatal injuries are 13.9 days and 69.4 days respectively.* To this must be added other costs arising from an accident. It stretches plausibility to assume that these are simply mistakes.

Bar Ilan and Sacerdote [15–17] provide near-decisive evidence that the alternative

explanations listed in Remark 2 for the Becker paradox, cannot explain the decision to run red traffic lights. It is quite clear that several of those explanations do not work because the punishment is self-inflicted; see the report by The Royal Society for the Prevention of Accidents [9] for a detailed discussion. A far more natural explanation is that the probability of an accident is low enough for stylized fact S3 to apply for many people. Thus, red traffic light running is simply caused by some individuals ignoring (or seriously underweighting) the very low probability of an accident. The *bimodal perception of risk* (see the section titled “A Possible Formalization of the Bimodal Perception of Risk”) then ensures that a fraction of the drivers do not run traffic lights. If the PWF incorporates S1 but not S3, then we should not observe any red traffic light running at all (Remark 3), which is contrary to the evidence.

Driving and Talking on Car Mobile Phones

Consider the usage of mobile phones by drivers in moving vehicles. Such an individual faces *potentially infinite punishment* (e.g., loss of one’s and/or the family’s life) with *low probability*, in the event of an accident. The Becker proposition applied to this situation would suggest that drivers of vehicles will not use mobile phones while driving or perhaps use hands-free phones, and so, avoid the self-inflicted punishment. Yet, evidence suggests that drivers use mobile phones in moving vehicles [18,19]; hence, this problem belongs to the general class of problems in the Becker paradox (see Remark 3 above). Evidence also suggests that hands-free phone equipment does not offer significantly more safety. A natural explanation of this class of problems is that individuals simply ignore or substantially underweight the low probability of an accident caused by driving and talking on mobile phones, as in stylized fact S3.

Other Examples

People were reluctant to employ seat belts prior to their mandatory use despite publicly available evidence that seat belts can make

the difference between surviving and dying in a car crash, or simply that they provide better safety. Prior to 1985, in the United States, only 10–20% of motorists wore seat belts voluntarily, hence, denying themselves *self-insurance* [20]. *Potentially fatal* car accidents may be perceived by individuals as *low probability events*, particularly if they are overconfident of their driving abilities. Overconfidence is supported from a wide range of contexts [7]. Reluctance to wear seat belts can, thus, be seen to be a special case of the general Becker paradox outlined in Remark 3, which requires the use of stylized fact S3 as a necessary condition for an explanation.

Even as evidence accumulated about the dangers of breast cancer (which has a *low unconditional probability but fatal consequences*) women took up the offer of breast cancer examination, only sparingly. In the United States, this only changed after the greatly publicized events of the mastectomies of Betty Ford and Happy Rockefeller [12, p. xiii, pp. 13–14]. It is immediate that this too is a special case of the Becker paradox that requires an incorporation of S3 for its resolution.

Conclusion from These Disparate Contexts

al-Nowaihi and Dhami [7–9] draw two main conclusion from the evidence.

1. Human behavior for very low probability events cannot easily be explained by the existing mainstream theoretical models of risk. EU and the associated auxiliary assumptions are unable to explain the stylized facts. Furthermore, the leading non-expected utility alternatives such as (*RDU*) and (*CP*) make the problem even worse for those events where stylized fact S3 has bite. (*PT*) on the other hand is able to account for S1 and S3; however, its treatment of S3 is at an informal/ heuristic level only; see particularly the criticisms in Birnbaum [21].
2. A natural explanation for these phenomena seems to be that individuals simply ignore or seriously underweight very low probability events (stylized fact S3).

PROBABILITY WEIGHTING FUNCTIONS (PWFS)

Stylized facts S1, S2, and S3 would seem, at least to us, to be the minimum requirements that a theory of risk should address. Most alternatives to EU that use nonlinear weighting of probabilities, such as *RDU*, *PT*, *CP* invoke the concept of a *PWF* to incorporate stylized facts S1 and S2. None of these theories can incorporate all three stylized facts S1, S2, and S3. We examine below emerging work of al-Nowaihi and Dhami [7–9], who propose *composite cumulative prospect (CCP) theory* that successfully addresses all three stylized facts S1, S2, and S3.

Remark 4. A PWF, by itself, is not a theory of risk. It needs to be embedded within the framework of a decision theory, say, *RDU*, *PT*, and *CP*, for it to have significant predictive content in concrete economic situations.

Definition 2. [PWF]. By a PWF we mean a strictly increasing function $w(p) : [0, 1] \xrightarrow{\text{onto}} [0, 1]$.

A simple proof, that we omit, can be used to demonstrate the following properties of a PWF; see al-Nowaihi and Dhami [7] for the proofs.

Proposition 1. A PWF has the following properties:

(a) $w(0) = 0$, $w(1) = 1$. (b) w has a unique inverse, w^{-1} , and w^{-1} is also a strictly increasing function from $[0, 1]$ onto $[0, 1]$. (c) w and w^{-1} are continuous.

Definition 3. The function, $w(p)$, (a) *infinitely overweights infinitesimal probabilities*, if $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$, and (b) *infinitely underweights near-one probabilities*, if $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = \infty$.

Definition 4. The function, $w(p)$, (a) *zero-underweights infinitesimal probabilities*, if

$\lim_{p \rightarrow 0} \frac{w(p)}{p} = 0$, and (b) *zero-overweights near-one probabilities*, if $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = 0$.

Definition 5. (a) $w(p)$ *finitely overweights infinitesimal probabilities*, if $\lim_{p \rightarrow 0} \frac{w(p)}{p} \in (1, \infty)$, and (b) $w(p)$ *finitely underweights near-one probabilities*, if $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} \in (1, \infty)$.

Definition 6. (a) $w(p)$ *positively underweights infinitesimal probabilities*, if $\lim_{p \rightarrow 0} \frac{w(p)}{p} \in (0, 1)$, and (b) $w(p)$ *positively overweights near-one probabilities*, if $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} \in (0, 1)$.

The following are some of the references where single-parameter PWFs are mentioned [22–27]. The two-parameter PWFs are mentioned in the following papers: [28–33]. The Prelec (1998) function appears to be the one with the strongest empirical support. To quote from Stott [[34], p. 102]: “the most predictive version of [cumulative prospect theory] has a power value curve, a single-parameter risky weighting function due to Prelec [31] and a Logit stochastic process.” It was also the first axiomatically derived PWF.

Definition 7. [31]. By the *Prelec function* we mean the PWF $w(p) : [0, 1] \rightarrow [0, 1]$ given by

$$w(0) = 0, w(1) = 1, \quad (4)$$

$$w(p) = e^{-\beta(-\ln p)^\alpha}, \quad 0 < p \leq 1, \alpha > 0, \beta > 0. \quad (5)$$

Definition 8. By the *standard Prelec function* we mean the Prelec function (Definition 7) with $\alpha < 1$.

The following Proposition can be easily checked.

Proposition 2. *The Prelec function (Definition 7) is a probability weighting function in the sense of Definition 2.*

We plot the Prelec PWF in Fig. 2; this is a plot of $w(p) = e^{-(\ln p)^{0.5}}$, that is, $\beta = 1$ and $\alpha = 0.5$. Since $\alpha < 1$, the Prelec function plotted in Fig. 2 is, in fact, a standard Prelec function (Definition 8).

The parameter α controls the convexity/concavity of the Prelec function. Between the region of strict convexity ($w'' > 0$) and the region of strict concavity ($w'' < 0$), there is a point of inflexion ($w'' = 0$). The parameter β in the Prelec function controls the location of the inflexion point relative to the 45° line. Sometimes, the respective roles of α and β are also referred to as the *curvature* and *elevation* properties of a PWF [29,35]. Not all PWFs allow for a clear separation between curvature and elevation. This is particularly the case for PWFs that involve one parameter rather than two parameters.

The full set of possibilities for the Prelec PWF, for different combinations of α, β is established in al-Nowaihi and Dhami [7]. A simple proof leads to the following result.

Figure 2. A plot of the Prelec (1988) function, $w(p) = e^{-(\ln p)^{1/2}}$.

Proposition 3. [7]

- (a) For $\alpha < 1$ the Prelec function, that is, the standard Prelec function (Definitions 7 and 8) (i) is inverse-S-shaped, (ii) infinitely overweights infinitesimal probabilities, that is, $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$, and (iii) infinitely underweights near-one probabilities, that is, $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = \infty$.
- (b) For $\alpha > 1$ the Prelec function (i) is S-shaped, (ii) zero-underweights infinitesimal probabilities, that is, $\lim_{p \rightarrow 0} \frac{w(p)}{p} = 0$, and (iii) zero-overweights near-one probabilities, that is, $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = 0$.

According to Prelec [[31], p. 505], the infinite limits in Proposition 3 (a) capture the qualitative change as we move from certainty to probability and from impossibility to improbability. On the other hand, they contradict stylized fact S3, that is, the observed behavior that people ignore events of very low probability and treat very high probability events as certain. These specific problems are avoided for $\alpha > 1$. However, for $\alpha > 1$, the Prelec function is S-shaped. This, however, is in conflict with stylized fact S1.

Remark 5. [Standard PWFs]. A large number of PWFs have been proposed, for example, those by Gonzalez and Wu [29], Lattimore Baker [30], and Prelec [31] (with $\alpha < 1$, that is, the standard Prelec function) [32,33]. They all overweight infinitesimal probabilities. We shall call these the standard PWFs. All these functions violate stylized fact S3.

Axiomatic Derivations of Prelec's PWF

Here, we overview three derivations of Prelec's function: Prelec [31] based on *compound invariance*, Luce [36] based on *reduction invariance*, and al-Nowaihi and Dhimi [37] based on *power invariance*.

We assume here that $0 \in X$, the set of outcomes, and we shall restrict ourselves to the special class of lotteries defined as follows.

Definition 9. Let $\mathbf{S} \subset \mathcal{L}$ be the subset of all lotteries of the forms (x) , (x, p_1) , $((x, p_1), p_2)$ and $((x, p_1), p_2), p_3)$, where $x \in X$ and $p_1, p_2, p_3 \in [0, 1]$.

To simplify notation, we shall refer to $((x, p_1), p_2)$ and $((x, p_1), p_2), p_3)$ by $(x; p_1, p_2)$ and $(x; p_1, p_2, p_3)$, respectively. Thus, (x) is the lottery whose outcome is x for sure, $(x; p_1)$ is the lottery whose outcomes are x with probability p_1 and 0 with probability $1 - p_1$, $(x; p_1, p_2)$ is the lottery whose outcomes are $(x; p_1)$ with probability p_2 and 0 with probability $1 - p_2$, and $(x; p_1, p_2, p_3)$ is the lottery whose outcomes are $(x; p_1, p_2)$ with probability p_3 and 0 with probability $1 - p_3$.

Given a strictly increasing function, $u : X \rightarrow \mathbb{R}$, and a PWF, w , we can extend u to a function, $U : \mathbf{S} \rightarrow \mathbb{R}$, by the following definition.

Definition 10. $U(x) = u(x)$, $U(x; p_1) = w(p_1)U(x)$, $U(x; p_1, p_2) = w(p_2)U(x; p_1)$, and $U(x; p_1, p_2, p_3) = w(p_3)U(x; p_1, p_2)$.

Definition 11. Let $\leq$ be the order on $\mathbf{S}$ induced by U , that is, for all $L_1, L_2 \in \mathbf{S}$, $L_1 \leq L_2 \Leftrightarrow U(L_1) \leq U(L_2)$.

Definition 12. [31]. The preference relation, $\leq$, satisfies *compound invariance* if, for all outcomes $x, y, x', y' \in X$, probabilities $p, q, r, s \in [0, 1]$, and integers $n \geq 1$, the following holds. If $(x, p) \sim (y, q)$ and $(x, r) \sim (y, s)$, then $(x', p^n) \sim (y', q^n)$ implies $(x', r^n) \sim (y', s^n)$.

Definition 13. [36]. The preference relation, $\leq$, satisfies *reduction invariance* if, for all outcomes $x \in X$, probabilities $p_1, p_2, q \in [0, 1]$ and $\lambda \in \{2, 3\}$: $(x; p_1, p_2) \sim (x; q) \Rightarrow (x; p_1^\lambda, p_2^\lambda) \sim (x; q^\lambda)$.

Definition 14. [37]. The preference relation, $\leq$, satisfies *power invariance* if, for all outcomes $x \in X$, probabilities $p, q \in [0, 1]$ and $\lambda \in \{2, 3\}$: $(x; p, p) \sim (x; q) \Rightarrow (x; p^\lambda, p^\lambda) \sim (x; q^\lambda)$ and $(x; p, p, p) \sim (x; q) \Rightarrow (x; p^\lambda, p^\lambda, p^\lambda) \sim (x; q^\lambda)$.

It is easy to check that for $w(p) = p$ (i.e., the EU case) *compound invariance*, *reduction invariance*, and *power invariance* are all satisfied. Hence, each of these constitutes a weakening (or generalization) of EU.

Proposition 4. [37]. *A PWF, w , is the Prelec PWF if, and only if, the induced preference relation, $\preceq$, satisfies either compound invariance, reduction invariance, or power invariance.*

From Proposition 4, all three axioms, *compound invariance*, *reduction invariance*, and *power invariance* are equivalent.

ADDRESSING STYLIZED FACT S1

Addressing stylized fact S1 requires a PWF that is inverse-S-shaped, that is, one that overweights low probabilities and underweights high probabilities. All the standard PWFs have this feature. In particular, this is true for the Prelec PWF if $\alpha < 1$, that is, what we called the *standard Prelec function* (Proposition 3(a)).

ADDRESSING STYLIZED FACT S2

There are two main ways of addressing S2. Either one uses *RDU* or *CP theory*. Quiggin's main insight in Quiggin [38,39] is that it is not individual probabilities that should be transformed (which gave rise to the violation of monotonicity reported in S2) but, rather, *cumulative probabilities*. When EU is applied to the transformed cumulative probabilities, we get what is now known as *RDU*.

In *RDU*, the decision maker uses Equation (3) with the decision weights generated as follows.

Definition 15. Consider the lottery $(x_1, p_1; x_2, p_2; \dots; x_n, p_n)$, where $x_1 < x_2 < \dots < x_n$. Let w be the PWF. For *RDU*, the *decision*

weights, π_i , are defined as follows.

$$\begin{aligned} \pi_n &= w(p_n), \\ \pi_{n-1} &= w(p_{n-1} + p_n) - w(p_n), \\ &\vdots \\ \pi_i &= w\left(\sum_{j=i}^n p_j\right) - w\left(\sum_{j=i+1}^n p_j\right), \\ &\vdots \\ \pi_1 &= w\left(\sum_{j=1}^n p_j\right) - w\left(\sum_{j=2}^n p_j\right) = w(1) \\ &\quad - w\left(\sum_{j=2}^n p_j\right) = 1 - w\left(\sum_{j=2}^n p_j\right). \end{aligned}$$

From Definition 15, we get that

$$\pi_j \geq 0 \text{ and } \sum_{j=1}^n \pi_j = 1. \quad (6)$$

Proposition 5. [3,38]. *A decision maker who uses RDU, never chooses stochastically dominated options (i.e., does not violate monotonicity). In other words, for an RDU decision maker there is no problem with explaining S2.*

A result analogous to that in Proposition 5 also holds for the case of *CP theory* [33,40,41]. In *CP*, the domain of outcomes is split into the domain of *gains* and the domain of *losses* by expressing each outcome relative to some *reference point*. We note here that the decision weights across the domain of gains and losses under *CP* do not necessarily add up to 1. This contrasts with the case of *RDU*, in which there is no conception of different domains of gains and losses; so the decision weights add up to 1. Since *CP* uses the cumulative weighting machinery from *RDU*, the following proposition holds.

Proposition 6. *A decision maker who uses CP does not choose stochastically dominated options. Hence, CP can address stylized fact S2.*

The PWF plays an important role in determining a rich set of attitudes toward risk

under CP. Under EU, attitudes to risk are determined purely by the curvature of the utility function. Under CP, however, the utility function is concave in the domain of gains and convex in the domain of losses [1]. Hence, it might be tempting to conclude that under CP the decision maker is risk averse in the domain of gains and risk loving in the domain of losses. This is not true because of the role played by the interaction of the PWF and the curvature of the utility function under CP, in determining attitudes to risk. The following fourfold pattern of risk preferences can be shown under CP [10]. The decision maker is risk loving for small probabilities in the domain of gains and non-small probabilities in the domain of losses. He/she is also risk averse for non-small probabilities in the domain of gains and small probabilities in the domain of losses.

ADDRESSING STYLIZED FACT S3

While RDU and CP in conjunction with, say, the standard Prelec function (Definitions 7 and 8), are able to explain S1 and S2, they are unable to address stylized fact S3.

al-Nowaihi and Dhami [7] make the ambitious proposal of combining the psychological richness of PT (in accounting for S3 in the editing phase) with the more satisfactory cumulative transformation of probabilities in CP. They combine PT and CP into a single theory, which they call *CCP theory*, which essentially combines the editing and decision phases of PT into a single phase, while retaining cumulative transformations of probability, as in CP. CCP successfully accounts for all three stylized facts S1, S2, and S3. It can explain everything that RDU and CP can, but the reverse is false.

An immediate implication of Proposition 3(a) is that the standard Prelec function ($\alpha < 1$) can explain S1 but not S3. From Proposition 3(b), we know that for $\alpha > 1$, the Prelec function is S-shaped, which explains S3 but contradicts S1. In order to explain S1, S2, and S3 using CCP, al-Nowaihi and Dhami [7] introduce a modification to the Prelec PWF in a manner that is consistent with the empirical evidence. They eliminate the discontinuities at the end points in Fig. 1 with

empirically founded as well as axiomatically founded behavior. They call their suggested modification as *composite Prelec weighting function* (CPF). Figure 3 depicts the general shape of CPF.

In Fig. 3, decision makers heavily underweight very low probabilities in the range $[0, p_1]$. Decision makers who use the weighting function in Fig. 3 would ignore very low probability events by assigning low subjective weights to them. Hence, in conformity with the evidence [7–9], they are unlikely to be dissuaded from “low-probability high-punishment” crimes, reluctant to buy insurance for very low probability events, reluctant to wear seat belts, reluctant to participate in voluntary breast screening programs, willing to run red traffic lights, and so on. For an even fuller description of behavior that accounts for the observed pattern of heterogeneity, one would need to incorporate further considerations such as those discussed in [7].

In the probability range $[p_3, 1]$, events are overweighted as suggested by Kahneman and Tversky [1, pp. 282–283]. In the middle segment, $p \in [p_1, p_3]$, the PWF is similar to the Prelec function with $\alpha < 1$, that is, a standard Prelec function successfully addresses S1.

For examples of the CPF, fitted to actual data, see al-Nowaihi and Dhami [7,8]. Owing to space limitations, we restrict ourselves to a brief, formal, description of the CPF. This implements the general shape of the CPF in Fig. 2. Define

$$\underline{p} = e^{-\left(\frac{\beta}{\beta_0}\right)^{\frac{1}{\alpha_0 - \alpha}}}, \quad \bar{p} = e^{-\left(\frac{\beta}{\beta_1}\right)^{\frac{1}{\alpha_1 - \alpha}}}. \quad (7)$$

Essentially, the CPF in Fig. 3 is described by segments from three different Prelec PWFs. The first is defined over the range $0 \leq p \leq \underline{p}$, the second is defined over the range $\underline{p} < p \leq \bar{p}$, and the third is defined over the range $\bar{p} < p \leq 1$. The choice of $\underline{p}$ and $\bar{p}$ will guarantee that the three segments are joined continuously.

Figure 3. The composite Prelec weighting function (CPF).

Definition 16. [7]. By the *CPF* we mean the PWF $w : [0, 1] \rightarrow [0, 1]$ given by

$$w(p) = \begin{cases} 0 & \text{if } p = 0 \\ e^{-\beta_0(-\ln p)^{\alpha_0}} & \text{if } 0 < p \leq \underline{p} \\ e^{-\beta(-\ln p)^\alpha} & \text{if } \underline{p} < p \leq \bar{p} \\ e^{-\beta_1(-\ln p)^{\alpha_1}} & \text{if } \bar{p} < p \leq 1, \end{cases} \quad (8)$$

where $\underline{p}$ and $\bar{p}$ are given by Equation (8) and

$$0 < \alpha < 1, \beta > 0; \alpha_0 > 1, \beta_0 > 0; \alpha_1 > 1, \beta_1 > 0, \\ \beta_0 < 1/\beta^{\frac{\alpha_0-1}{1-\alpha}}, \beta_1 > 1/\beta^{\frac{\alpha_1-1}{1-\alpha}}. \quad (9)$$

Note the following. The first segment ($0 \leq p \leq \underline{p}$) of the CPF is identical to the Prelec function $e^{-\beta_0(-\ln p)^{\alpha_0}}$, which is S-shaped because $\alpha_0 > 1$. The second segment ($\underline{p} < p \leq \bar{p}$) is identical to the standard Prelec function $e^{-\beta(-\ln p)^\alpha}$, which is inverse-S shaped because $\alpha < 1$. The third, and final, segment of the CPF ($\bar{p} < p \leq 1$) is identical to the Prelec function $e^{-\beta_1(-\ln p)^{\alpha_1}}$, which is S-shaped because $\alpha_1 > 1$.

Proposition 7. [7]. *The CPF is a PWF.*

Define p_1, p_2, p_3 that correspond to the notation used for the general shape of a CPF in Fig. 3.

$$p_1 = e^{-\left(\frac{1}{\beta_0}\right)^{\frac{1}{\alpha_0-1}}}, p_2 = e^{-\left(\frac{1}{\beta}\right)^{\frac{1}{\alpha-1}}}, \\ p_3 = e^{-\left(\frac{1}{\beta_1}\right)^{\frac{1}{\alpha_1-1}}}. \quad (10)$$

Proposition 8. [7]. (a) $p_1 < \underline{p} < p_2 < \bar{p} < p_3$. (b) $p \in (0, p_1) \Rightarrow w(p) < p$. (c) $p \in (p_1, p_2) \Rightarrow w(p) > p$. (d) $p \in (p_2, p_3) \Rightarrow w(p) < p$. (e) $p \in (p_3, 1) \Rightarrow w(p) > p$.

By Proposition 7, the CPF in Equations (9) and (10) is a PWF in the sense of Definition 2. By Proposition 8, a CPF overweights low probabilities, that is, those in the range (p_1, p_2) , and underweights high probabilities, that is, those in the range (p_2, p_3) . Thus, it accounts for stylized fact S1. But, in addition, and unlike all the standard PWFs, it underweights probabilities near 0, that is, those in the range $(0, p_1)$, and overweights probabilities close to 1, that, those in the range $(p_3, 1)$ as required in S3.

Proposition 9. [7]. *The CPF (9):*

- (a) *zero-underweights infinitesimal probabilities, that is, $\lim_{p \rightarrow 0} \frac{w(p)}{p} = 0$ (Definition 4a),*
- (b) *zero-overweights near-one probabilities, that is, $\lim_{p \rightarrow 1} \frac{1-w(p)}{1-p} = 0$ (Definition 4b).*

Remark 6. [Axiomatic foundations of CPF-I]. The axiomatic foundations for the CPF in al-Nowaihi and Dhimi [7] rely on the axiom of *local power invariance*. This axiom, in turn, is a modification of the axiom of *power*

invariance used in al-Nowaihi and Dhami [37] to axiomatically derive the Prelec PWF.

Remark 7. [Axiomatic foundations of CPF-II]. Several axiomatizations of RDU allow for additive separability between terms that multiply utility with probability weights [3,4,11]. These axiomatizations are discussed elsewhere in the encyclopedia (see the section titled “Foundations and Principles of Decision Analysis”) and lie outside the scope of this entry. However, Abdellaoui [3] and Wakker [4] assume increasing PWFs; thus, CPF is consistent with them. In order to ensure concavity or convexity of the weighting function, these contributions introduce additional global auxiliary conditions such as probabilistic risk aversion. See, in particular, Wakker [11], who allows for a preference axiomatization of convex capacities. This allows for a weighting function that is either concave or convex throughout; hence, these cannot, simultaneously address stylized facts S1 and S3. Diecidue *et al.* [42] introduce local conditions that allow for probabilistic risk aversion to vary over the probability interval $[0, 1]$. For one set of parameter values, they can address S1 (in which case $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$) while for the complementary set of parameter values, they can address S3 (in which case $\lim_{p \rightarrow 0} \frac{w(p)}{p} = 0$). However, their proposal does not simultaneously address S1 and S2.

Remark 8. [Axiomatic foundations of CPF-III]. An advantage of the axiomatization of CPF by al-Nowaihi and Dhami [7] is that from the class of all increasing PWFs, which is an assumption made in all axiomatizations, they choose a particular parametric member, the CPF. Thus, the CPF (and the associated axiomatization that relies on local power invariance) allows for a sharper prediction, which turns out to be consistent with the evidence. Therefore, relative to the other axiomatizations, the work by al-Nowaihi and Dhami [7] addresses the further question “what extra axioms are needed to get more specific (and, hence, more predictive) PWFs?”

Definition 17. [7]. Otherwise standard CP, when combined with a CPF, is called *CCP theory*. Analogously, otherwise standard RDU, when combined with a CPF, is referred to as *composite rank-dependent utility* (CRDU).

al-Nowaihi and Dhami [7] prove the following proposition, whose intuition would by now be largely clear to the reader from our discussion of the CPF. Since probabilities in the middle ranges are weighted as in Prelec [31], stylized fact S1 is explained. Since cumulative transformations of probability are undertaken in CCP and CRDU, S2 is explained. And because of the property of the CPF in Proposition 9, S3 is explained.

Proposition 10. [7]. *CCP and CRDU can explain S1, S2, and S3.*

Blavatskyy [43] shows that the St. Petersburg paradox re-emerges under CP. al-Nowaihi and Dhami [7] show that the St. Petersburg paradox can be resolved under CCP mainly through the role played by the CPF. Rieger and Wang [32] also propose a PWF that resolves the St. Petersburg paradox, but it cannot explain stylized fact S3.

In comparison to CRDU, CCP, in addition, incorporates reference dependence, loss aversion, and richer attitudes toward risk. Hence, it can explain everything that CRDU can, but the converse is false. Furthermore, since CCP explains S1, S2, and S3, while CP (and RDU) can only explain S1 and S2, CCP can explain everything that CP (and RDU) can, but the converse is false. In light of these observations, it is interesting to note the observation in Machina [44] that “RDU is currently the most popular decision theory under risk.”

THE ALLAIS PARADOX UNDER CP AND CCP

Consider the Allais paradox as a *common consequence effect*. We omit a discussion of the *common ratio form*, as similar comments apply in that case. Consider the following two pairs of lotteries where outcomes are

presented relative to the status quo (so the reference point is 0):

$$a_1 = (1, 1); a_2 = (0, 0.01; 1, 0.89; 5, 0.1), \quad (11)$$

$$a_3 = (0, 0.89; 1, 0.11); a_4 = (0, 0.9; 5, 0.10). \quad (12)$$

Allais (1953) conjectured that decision makers would prefer a_1 to a_2 , while at the same time preferring a_4 to a_3 (this conjecture has been confirmed by a large number of experiments). As is well known, this pattern of preferences is violated under EU (on account of a violation of the independence axiom). Notice that all outcomes in the lotteries in Equations (12) and (13) are in the domain of gains. Let the utility function be of the usual power form, $u(x) = x^\gamma$, with $\gamma = 0.88$ as suggested by the experimental data [33]. Then, under CP (and also CCP), the stated pattern of preferences implies the following:

$$a_1 \succ a_2 \Leftrightarrow 1^{0.88} > [w(0.89 + 0.1) - w(0.1)]1^{0.88} + w(0.01)5^{0.88}, \quad (13)$$

$$a_4 \succ a_3 \Leftrightarrow w(0.1)5^{0.88} > w(0.11)1^{0.88}. \quad (14)$$

Suppose that under CP, the weighting function is the Prelec function with parameters $\alpha = 0.5$ and $\beta = 1$; so, $w(p) = e^{-(\ln p)^{0.5}}$. Thus, we can rewrite Equations (14) and (15) as

$$a_1 \succ a_2 \Leftrightarrow 1^{0.88} > \left[e^{-(\ln 0.99)^{0.5}} - e^{-(\ln 0.1)^{0.5}} \right] 1^{0.88} + w(0.01)5^{0.88}. \quad (15)$$

which is true.

$$\begin{aligned} a_4 \succ a_3 &\Leftrightarrow e^{-(\ln 0.1)^{0.5}} 5^{0.88} \\ &> e^{-(\ln 0.11)^{0.5}} 1^{0.88} \end{aligned} \quad (16)$$

which is also true. Hence, under CP, nonlinear weighting of probabilities allows for an explanation of the Allais paradox (in the common consequence effect form) that could not be explained under EU.

Remark 9. Can the Allais paradox (in the common consequence and common ratio effects forms) also be explained under CCP? From Definition 16 and Equation (9), we know that over the probability range $[\underline{p}, \bar{p}]$, CPF and CCP are identical. Hence, for lotteries that only have probabilities in the interval $[\underline{p}, \bar{p}]$ both theories make identical predictions. The intuition is that these probabilities are sufficiently nonextreme that only stylized fact S1 has any bite. Stylized fact S3 has bite only if probabilities lie outside the range $[\underline{p}, \bar{p}]$, say, in the two extreme probability intervals $[0, p_1]$ and $[p_3, 1]$ (see Fig. 3, Definition 16, and Equation (9)). In these two intervals, different segments of the Prelec function apply (because the CPF is made up of three different segments of a Prelec function) and one simply needs to alter the relevant values of α, β in inequalities such as Equations (16) and (17) above and recheck them.

In the light of Remark 9, it becomes important to compute $\underline{p}, \bar{p}$. In an ideal world one would obtain data from the relevant context and problem in order to elicit the values $\underline{p}, \bar{p}$. Here, we rely on the computation made by al-Nowaihi and Dhami [7] of these values based on data in Kunreuther *et al.* [12]. From two separate sets of data, the farm and the urn experiments, respectively, al-Nowaihi and Dhami [7] derive the following two sets of values for the range $(\underline{p}, \bar{p})$: $(0.05, 0.95]$ and $(0.25, 0.75]$.

The probabilities involved in the two comparisons in Equations (16) and (17) are 0.33, 0.34, and 0.99. The last of these probabilities lies outside the upper limit of both ranges $(0.05, 0.95]$ and $(0.25, 0.75]$. This does not affect the comparison in Equation (17) but does affect the comparison in Equation (16). For the urn and the farm experiments, al-Nowaihi and Dhami [7] show that the respective values of (α, β) for the upper segment of the Prelec function in the CPF are $(2, 6.4808)$ and $(2, 86.081)$. We now apply these values to the comparison in Equation (16), sequentially, for the urn and farm

experiments.

$$\text{Urn: } a_1 \succ a_2 \Leftrightarrow 1^{0.88} > \left[e^{-6.4808(-\ln 0.99)^2} - e^{-(\ln 0.1)^{0.5}} \right] 1^{0.88} + w(0.01)5^{0.88},$$

which is true.

$$\text{Farm: } a_1 \succ a_2 \Leftrightarrow 1^{0.88} > \left[e^{-86.081(-\ln 0.99)^2} - e^{-(\ln 0.1)^{0.5}} \right] 1^{0.88} + w(0.01)5^{0.88},$$

which is also true. Hence, the Allais paradox in common consequence effect form also holds true for CCP when we use a CPF that is fitted to the data in Kunreuther *et al.* [12]. We emphasize that we have not provided a proof that the Allais paradox will necessarily hold under CCP for all parameter values. Ideally one should have experimental data for the particular situation and then proceed along the lines of Remark 9 to check the resolution of the paradox.

A COMPARISON OF CCP WITH CONFIGURAL WEIGHTS MODELS

We now compare CCP with the class of *configural weight models*, which are reviewed elsewhere in the Encyclopedia (see the section titled “Foundations and Principles of Decision Analysis”). So we shall be brief and keep references to a minimum. The interested reader can directly consult Birnbaum [21] for an exhaustive set of references and a recent survey of these models.

Configural weight models, like several other alternatives to EU, nonlinearly weight probabilities of outcomes. In these models, one first writes down the decision tree corresponding to the problem. Consider some lottery, L , that has n possible consequences that arise from the different *branches* of the tree, ordered as, $x_n \leq x_{n-1} \leq \dots \leq x_2 \leq x_1$ with associated probabilities $p_n, p_{n-1}, \dots, p_2, p_1$. Outcome x_j is then said to have *rank* j , $j = 1, 2, \dots, n$ (one could use the convention $x_1 \leq x_2 \leq \dots \leq x_{n-1} \leq x_n$ but in this case the rank of the j th number in the list (counting from the left) will be $n - j$).

THE RANK-AFFECTED MULTIPLICATIVE WEIGHTS MODEL (RAM)

Using Equation (8) in Birnbaum [21], in the *rank-affected multiplicative weights model* (RAM), the utility of lottery, L , is given by

$$\text{RAM}(L) = \frac{\sum_{i=1}^n a(i, n, s) t(p_i) u(x_i)}{\sum_{j=1}^n a(j, n, s) t(p_j)}. \quad (17)$$

Indices i, j denote the *rank* of the outcome (defined above). s is the *augmented sign* of the branch's consequence (positive, zero, or negative). $t(p)$ is an increasing function of p , which typically takes the form

$$t(p) = p^\gamma; 0 < \gamma < 1. \quad (18)$$

The utility function $u(x)$ typically takes the power form

$$u(x) = x^\beta; 0 < \beta < 1. \quad (19)$$

$a(i, n, s)$ is the *rank and sign augmented branch weight* corresponding to the outcome that has rank i . For two-branch gambles, for example, the lottery $L = (0, 0.5; 100, 0.5)$, the branch corresponding to the lower outcome ($\$0$) is associated with $a = 2$ and the higher outcome is associated with $a = 1$. For m branch gambles, such that $m \geq 3$, the weights are simply the ranks of the outcomes for that branch. For example, for the set of outcomes, $x_m \leq x_{m-1} \leq \dots \leq x_1$, the weights (the a 's) are $m, m-1, m-2, \dots, 1$. Thus, lower outcomes are given higher weights, which is one of the main features of the model. From Equation (18) the weight associated with outcome x_i is

$$w(p_i) = \frac{a(i, n, s) t(p_i)}{\sum_{j=1}^n a(j, n, s) t(p_j)}.$$

Using Equation (19), this can be written as

$$w(p_i) = \frac{1}{1 + \sum_{j \neq i} \frac{a(j, n, s)}{a(i, n, s)} \left(\frac{p_j}{p_i} \right)^\beta}. \quad (20)$$

From Equation (21) $w(0) = 1$ and $w(1) < 1$. So this does not satisfy the assumptions of a PWF. In particular, from Equation (21)

$$\frac{w(p_i)}{p_i^\gamma} = \frac{1}{p_i^\gamma + \sum_{j \neq i} \frac{a(j, n, s)}{a(i, n, s)} p_j^\gamma}.$$

Since $a(i, n, s)$ is nonzero and $\frac{a(j, n, s)}{a(i, n, s)}$ is finite,

$$\lim_{p_i \rightarrow 0} \frac{w(p_i)}{p_i^\gamma} = \frac{1}{\sum_{j \neq i} \frac{a(j, n, s)}{a(i, n, s)} p_j^\gamma},$$

which is finite. Hence, extremely low probabilities are not ignored, which contradicts stylized fact S3.

TRANSFER OF ATTENTION IN EXCHANGE (TAX) MODELS

In the *transfer of attention in exchange (TAX) models*, the decision maker is assumed to possess a fixed amount of limited attention. Owing to this, the decision maker transfers weight from higher ranked to lower ranked outcomes. Consider a *three-branch* lottery, L , given by $L = (x_1, p_1; x_2, p_2; x_3, p_3)$. Then, from Equation (10) in Birnbaum [21] we get that the utility of this lottery to the decision maker under TAX is given by

$$\text{TAX}(L) = \frac{w_1 u(x_1) + w_2 u(x_2) + w_3 u(x_3)}{w_1 + w_2 + w_3}, \quad (21)$$

where

$$w_1 = t(p_1) - \frac{2}{4} \delta t(p_1); w_2 = t(p_2) - \frac{1}{4} \delta t(p_2) + \frac{1}{4} \delta t(p_1); w_3 = t(p_3) + \frac{1}{4} \delta t(p_1) + \frac{1}{4} \delta t(p_2). \quad (22)$$

$t(p)$ continues to be given in Equation (19) and $\delta > 0$ is some constant. In this version of the TAX model, also known as the *special TAX model*, one transfers a fixed amount of probability weight from a higher outcome, proportionately, to lower outcomes. Thus, $w_1 + w_2 + w_3 = t(p_1) + t(p_2) + t(p_3)$. From w_1 in Equation (23), it follows that the weight on the highest outcome, x_1 , is reduced by $\frac{2}{4} \delta t(p_1)$

and each of the lower two outcomes gains one-half of this weight. Similarly, the middle ranked outcome, x_2 , loses weight $\frac{1}{4} \delta t(p_2)$ which is gained by the worse outcome, x_3 .

From Equations (19) and (23), we can compute the ratio of weights to probabilities as

$$\begin{aligned} \frac{w_1}{p_1^\gamma} &= 1 - \frac{1}{2} \delta; \frac{w_2}{p_2^\gamma} = 1 - \frac{1}{4} \delta + \left(\frac{p_1}{p_2}\right)^\gamma; \\ \frac{w_3}{p_3^\gamma} &= 1 + \frac{1}{4} \delta \left(\frac{p_1}{p_3}\right)^\gamma + \frac{1}{4} \delta \left(\frac{p_2}{p_3}\right)^\gamma. \end{aligned}$$

We assume that $0 < \delta \leq 2$ so that all weights are positive. There are three possibilities: (i) p_1 is the lowest probability. (ii) p_2 is the lowest probability. (iii) p_3 is the lowest probability. Since $t(p)$ is given in Equation (19), it follows that in these three cases, respectively,

$$\begin{aligned} \lim_{p_1 \rightarrow 0} \frac{w_1}{p_1^\gamma} &= 1 - \frac{1}{2} \delta \in (0, 1]; \lim_{p_2 \rightarrow 0} \frac{w_2}{p_2^\gamma} = \infty; \\ \lim_{p_3 \rightarrow 0} \frac{w_3}{p_3^\gamma} &= \infty. \end{aligned} \quad (23)$$

From Equation (24), we see again that stylized fact S3 is violated for this class of theories.

THE GAINS DECOMPOSITION UTILITY (GDU) MODEL

This model is set out as Equations (11)–(13) in Birnbaum [21]. The idea is to reduce multi-branch lotteries to simple, two-branch, lotteries. For instance, consider the binary lottery $L_2 = (x_1, p; x_2, 1 - p)$ such that $x_1 \leq x_2$. Then, under the *gains decomposition utility (GDU) model*, the utility of this binary lottery is

$$\text{GDU}(x_1, p, x_2) = w(p)u(x_1) + (1 - w(p))u(x_2). \quad (24)$$

Notice that the decision weights are formed exactly as under RDU. Three-branch lotteries such as $L_3 = (x_1, p_1; x_2, p_2; x_3, p_3)$ are then evaluated as follows. First, a choice is made between the lowest outcome x_3 and the binary lottery that comprises the remaining two outcomes. Probabilities are renormalized

so that they add up to 1 in the binary lottery. In other words, L_3 is treated as

$$\begin{aligned} L_3 &= \left(\left(x_1, \frac{p_1}{p_1 + p_2}; x_2, 1 - \frac{p_1}{p_1 + p_2} \right); \right. \\ &\quad \left. x_3, 1 - p_1 - p_2 \right) \Leftrightarrow L_3 \\ &= (L_2, p_1 + p_2; x_3, 1 - p_1 - p_2). \end{aligned} \quad (25)$$

Thus, L_3 is transformed into a binary lottery, which can be evaluated using Equation (25) as follows:

$$\begin{aligned} \text{GDU}(L_3) &= w(p_1 + p_2) \text{GDU} \left(x_1, \frac{p_1}{p_1 + p_2}, x_2 \right) \\ &\quad + [1 - w(p_1 + p_2)] u(x_3). \end{aligned}$$

In terms of the weighting of outcomes, this is exactly like RDU. The weighting functions used in this theory are the standard weighting function (e.g., the standard Prelec function is used by Birnbaum [21]). Thus, $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$ and, so, stylized fact S3 cannot be addressed by this theory either.

Remark 10. A great deal of the differences in prediction between CP (and by implication, CCP) and the configural weight models arise in the case of *event splitting* [21]. This occurs when there are two identical outcomes in a lottery. However, for the examples listed in the section titled “Evidence for S3”, event splitting does not occur [7–9].

Remark 11. For lotteries of the form $(x, p; y, 1 - p)$, where $x < 0 < y$, Birnbaum [21] reports that CP and TAX give close results. So, for TAX to be different, we need lotteries with, at least, three outcomes. More generally, it is difficult to distinguish between CP and TAX within the probability triangle. These observations are important. First, they show that where CP is successful (the experiments reported by Kahneman and Tversky [1,33] and, more generally, events that can be represented in the probability triangle), TAX is also successful. But for the “new” paradoxes, Birnbaum [21] argues that TAX succeeds where CP fails. In many

applications that involve use of stylized fact S3, configural weights models are likely to fail as do EU, RDU, and CP, while CCP is likely to succeed in these cases. In these cases, the configural weight models can benefit by incorporating stylized fact S3 by using a composite Prelec PWF.

A POSSIBLE FORMALIZATION OF THE BIMODAL PERCEPTION OF RISK

There is evidence of a *bimodal perception of risks* [13]. For the evidence, see Schade *et al.* [45]. Type-I individuals focus more on the probability of a loss while Type-II individuals focus more on the size of the loss.

Type-I individuals focus on the probability and do not pay attention to losses whose probability falls below a certain threshold. Hence, S3 applies to these individuals. Their behavior is explained by CCP and the CPF probability weighting functions. These individuals are the ones that jump red traffic lights, do not take out adequate insurance against low probability hazards, do not wear seat belts unless mandatory, are not deterred from crime by low probability capital punishment, and so on.

For Type-II individuals, the size of the loss is relatively more salient. They appear to fear large losses, even for extremely small probabilities. This could be accounted for by the standard Prelec function, since for that probability weighting function, $\lim_{p \rightarrow 0} \frac{w(p)}{p} = \infty$.

Whatever the underlying cause of their behavior, it appears to be best described by CP and the standard Prelec function. Indeed, since the underlying causes can be complex, assigning such individuals a Prelec function is a parsimonious and useful representation of that complexity.

In line with the evidence on the bimodal perception of risk, one may conjecture two subpopulations of humans. One whose behavior under risk is described by the standard Prelec probability weighting function and standard CP (Type-II individuals)

and the other by the composite Prelec probability weighting function and CCP (Type-I individuals). Although the focus of this section has been on the latter, our work should be regarded as complementing the (mainstream) Becker approach, thus extending it into areas it hitherto has been unsuccessful.

Example 1. Recall the discussion in the section titled “Evidence from Jumping Red Traffic Lights.” The reader may, rightly, wonder that if individuals ignore very low probabilities, then why does not everyone engage in, say, red traffic light running? There are many potential explanations. For instance, some individuals are simply “law abiding” under any circumstances. Others might be daunted by the possibility of losing their lives. Individuals who do not run traffic lights (for whatever reasons) behave “as if” they use the Prelec weighting function who infinitely overweight infinitesimal probabilities so the potential loss even with a low probability is very salient. Individuals who, on the other hand, run red traffic lights behave “as if” they satisfy the *CPF*. Such individuals ignore the very low probability of an accident and, so, the potentially infinite loss is not salient. This comment applies in spirit to all sorts of Becker paradoxes mentioned in this article.

Acknowledgments

Dr. Sanjit Dhami would like to acknowledge a one semester study leave provided by the University of Leicester. He also wishes to thank the International School of Economics (ISET) at Tbilisi State University, Georgia, for their excellent hospitality and academic environment during the time that he was a visiting Professor in the spring/summer of 2010. We are grateful to the editor and the referee for useful comments and suggestions.

PROBLEM STRUCTURING FOR MULTICRITERIA DECISION ANALYSIS INTERVENTIONS

INTRODUCTION

Multicriteria decision analysis (MCDA), a methodology for supporting decision making when multiple objectives have to be pursued [1–3], has been extensively used to support a wide variety of complex decision problems [4,5]. While the literature on axiomatic aspects of multicriteria decision analysis models is extensive, much less attention has been devoted to the process of structuring these models, with few exceptions [6–8].

The task of structuring MCDA models in real-world interventions is far from trivial. This is mainly due to the intrinsic complexity of the models, where several objectives have to be articulated, defined, and measured by attributes. Furthermore, the definition of a set of alternatives to be evaluated is not always straightforward, as decision makers may struggle to think creatively about the problem and consider innovative alternatives.

At a broader level, much of the MCDA literature neglects the role of problem structuring as a prelude to the structuring of an MCDA model, a phase of the intervention whose proper management is absolutely crucial if both the decision analysts and the decision analysis are to have some effect on the organization.

In this article, we discuss problem structuring for MCDA interventions. There is a

limited literature on how to structure MCDA models, and this will be reviewed here. Furthermore, while there is a large body of literature on problem structuring and on problem-structuring methods, most of it is disconnected from the mainstream MCDA literature. We will build on this body of work to give a coherent perspective on problem structuring for MCDA, which we hope will be useful for both MCDA researchers and practitioners.

The chapter is structured as follows: we start by discussing two key problem-structuring tasks concerning the earlier stages of an MCDA intervention. The subsequent section reviews general guidelines for structuring MCDA evaluation models. In the final section, we build on the preceding sections to propose a general framework for conducting MCDA interventions, in which problem structuring plays a significant role. The chapter ends with concluding remarks and some directions for further research in the field.

STRUCTURING THE PROBLEM SITUATION

There are two main problem-structuring tasks faced by decision analysts when conducting MCDA interventions: *defining the problem*, and *scoping participation*. Below we discuss each of these tasks and comment on the challenges the decision analyst may encounter when carrying them out, together with a set of tools/techniques that could be used to facilitate their achievement. Although, in the discussion that follows, we present each problem-structuring task separately, it is worth noting that in practice these tasks are not necessarily undertaken in a linear fashion. Rather, there are two “modes” of problem structuring between which the decision analyst is continually “cycling” during the early stages of an MCDA intervention.

Defining the Problem

Given the significance of problem formulation

in organizational decision making [9–12], it is surprising that the literature on MCDA has devoted relatively minor attention to the processes of articulating and defining a multicriteria problem. It seems that the underlying assumption is that arriving at a well-structured multicriteria decision problem is somehow a relatively trivial task. There is also a widespread belief among many practitioners that structuring a decision problem is more “art than science” and that it can best be learned through experience. This view suggests that experienced analysts are able to recognize familiar patterns or structures of problems, and use them as templates to build their decision models [13]. Our experience as researchers and consultants, however, suggests that the use of decision analytic structures are well suited to problem situations that are clearly defined, but less so when they are ill-structured or ‘messy’ [14]. In such situations, attempts to impose a structure too early in the intervention can lead to focusing on and solving the ‘wrong problem’ and thus incurring in what is known as the *Type III* error [15].

Indeed empirical research has shown that the definition of problems, particularly those of the ill-structured type, is not given but continually negotiated among members of the organization before and during an intervention [16]. This process of negotiation can be conceptualized as follows. First, managers are constantly striving to make sense of their internal and external environments in order to manage and control their organizations [17]. This sense-making process is aided with the help of a unique mental framework that is developed through experience, and which includes systems of beliefs and values. A ‘problem’ emerges when the use of such a mental framework, to make sense of a particular situation, leaves the manager uneasy or dissatisfied because she/he does not know how to deal with that situation. Because different managers will experience different problems by applying their own unique mental frameworks to what might be thought of as the same situation, the decision analyst will not be able to think and talk about the ‘problem’ without ascribing an owner or owners to it.

Second, the problem which will eventually be presented to the analyst is the result of a process of ‘problem framing’ within the organization, most typically within a team of managers. As Eden and Sims aptly illustrate, a manager who wishes to get others in the team to take on a problem she/he has identified as being the team’s, “...will present the problem in such a way as to make it apparent that there are gains to be had or losses to be averted for other members of the team by solving this problem. He (sic) may seek to show some member of the team that a solution to his (the initial problem’s definer) problem would also solve some different problem, which he believes this member to be experiencing. ...he may define his problem to be in line with other problems which seem to be being experienced at that time. ... (or) express concern and commitment about some problem being stated by another member in the hope of getting some concern and commitment about his problem in return” (16, p. 121).

Thus, we might expect that when the analyst starts an MCDA intervention with a given problem situation presented by the client, the reality is that other versions of the same situation are likely to exist. These other versions will become apparent as the analyst listens to others in the organization. One challenge for the analyst at this stage is then not so much to model what will become the actual multicriteria decision problem to be solved, but to identify and model the different perceptions of the *problem situation* held by different managers. Several problem-structuring tools are available to support this task. These include, for example, cognitive mapping [18,19]; soft systems methodology [20,21]; dialog mapping [22]; strategic choice approach [23], and group model building [24,25]. (For an overview of these tools see Ref. 10.)

Most of these tools have been developed to capture multiple aspects of a problem situation, including objective and subjective ones. This is important because when managers define a problem situation, it will be defined in their own language and based on their own interpretations of the situation, their own experience or expertise and their own value

Figure 1. An example of a cognitive map, representing strategies for growth of an organization.

systems. A problem situation defined in this way will thus include factors that may not be typically regarded as legitimate variables in a standard MCDA modeling project, but that are nevertheless important if the analyst wishes to understand the needs and concerns of any particular client or client group. The challenge for the decision analyst is, therefore to be able to formally map aspects of the problem situation in terms of the concepts used by the client. For if there is a doubt in the client's mind about whether correct concepts have been taken into account, she/he is unlikely to believe in the solution to the problem, let alone act upon it [16].

For example, Fig. 1 illustrates a way to capture a client's understanding of a problem using the client's own concepts. The figure shows the beginning of a cognitive map that contains different aspects of a problem faced by an organization operating in the learning and professional development sector. Here the client is concerned about the growth of the organization, which eventually led to a multicriteria evaluation of strategic priorities at a later stage in the intervention. Nodes in the map contain statements describing different aspects of the problem. The links between

the statements denote means–end chains of arguments. For example, the “regeneration of profiling instrument” (top right in the map) is seen by this client as a way to get partners to “sign license agreements” (center right in the map).

The recognition that problem definition in organizations involves negotiation between managers with multiple world-views [20] about the problem has some practical implications for the analyst. First, if the MCDA intervention is intended to have some effect on the organization, the decision analyst may need to discuss a redefinition of the problem with the client before trying to help. The structuring tools cited above can all assist in this process [10]. Secondly, when working with members of a client group that have different views or interpretations of the problem situation of interest, the analyst must choose whose interpretation to pay attention to. The choice does not necessarily imply favoring one particular interpretation over another. Rather, it is about focusing on some combination of interpretations which for reasons that are explained later in the chapter, will often be a reflection of the analyst's understanding of the key stakeholders of the organization.

Figure 2. An example of a power–interest grid of stakeholders when considering strategies for growth of an organization.

Once the problem situation has been defined and agreed with the client or client group, the decision analyst should be in a good position to identify a particular decisional element of the situation upon which a relevant multicriteria evaluation model can be built. A quite useful tool at this stage is Keeney's concept of decision framing [6], which connects the strategic objectives of the organization with the fundamental objectives for the particular decision and the alternatives to be considered [as illustrated by Barcus and Montibeller [26]]. However, before proceeding, the decision analyst must scope the required levels of participation needed for the subsequent stages of the intervention. This aspect is discussed next.

Scoping Participation

Nutt conducted a careful analysis of 400 decisions in a variety of organizations and found that almost half of them 'failed' in terms of implementation (e.g., not implemented or only partially implemented) or the achieved results (e.g., poor results rather than good results) [27]. He discovered that the overriding reason for these failures was due, in large part, to the failure of decision makers to attend to the interests and information held by the *key stakeholders* of the organization. Although several definitions of stakeholders are possible [28], we conceptualize them here as those individuals, or groups, who have the power to affect the decision under consideration; or those groups that are affected, or perceived to be affected,

by the decision. This broad definition thus considers the internal as well as the external stakeholders of the organization.

Within the context of an MCDA intervention, attention to stakeholders is needed to assess and enhance political feasibility of decision implementation. Attention to stakeholders is also important to satisfy those involved in, or affected by, the decision that the intervention has followed rational, fair, and legitimate procedures. This does not imply that all possible stakeholders should be satisfied by or involved in the intervention; only that the key stakeholders must be. As in the case of defining the problem, the choice of which stakeholders are "key" should be the result of a discussion between the client and the analyst.

In the literature, there are several tools available for stakeholder analysis [28,29]. The most widely used techniques include the power–interest grid, star diagram, and stakeholder influence map [17]; and stakeholder–issue interrelation diagram and problem-frame stakeholder maps [28]. For example, Fig. 2 shows a power–interest grid for the problem situation discussed earlier. The grid arrays stakeholders on a two-by-two matrix, where the dimensions are the stakeholder's interest or stake in the decision at hand (i.e., they care about the decision or are affected by it), and the stakeholder's power to affect its implementation or impact. Four broad categories of stakeholders are shown in Fig. 2: 'players' who have both, an interest and significant power (e.g., Northern

European partners); ‘subjects,’ who have an interest but little power (e.g., North American partners); ‘context setters,’ who have power but little direct interest (e.g., regulatory agencies); and the ‘crowd,’ which consists of stakeholders with little interest or power. The grid allows the decision analyst to determine which players’ interests and power bases must be taken into account in order to address the decision at hand.

Whichever stakeholder identification technique is used, the actual process of choosing which stakeholders to involve in the intervention is often the result of several iterations along the following generic stages [28]:

- The analyst and client initiate the process by doing a preliminary stakeholder analysis, using any of the analysis techniques cited above. This step is useful in helping the client to think strategically about how to create the conditions needed for the intervention to reach a successful outcome.
- After reviewing the results of this analysis, a larger group of stakeholders can be assembled if judged appropriate. The assembled group should be asked to brainstorm the list of stakeholders, who might need to be involved in the intervention. Again, many of the techniques cited above might be used as a starting point. After this analysis has been completed, the analyst should encourage the group to think carefully about who is not at the meeting but that should be at subsequent meetings during the intervention. The analyst should ask the group to carefully think through the positive and negative consequences of involving—or not—other stakeholders or their representatives, and in what ways to do so.
- Last, both analyst and client finalize the various groups, who will have some role to play in the intervention. These will typically include the sponsors and champions, a coordinating group, a core decision analysis team, and various advisory or support groups [23].

The above process should be designed by the decision analyst to gain needed information, build political acceptance, and address some important questions about legitimacy, representation, and credibility [28]. However, the analyst should encourage the client to include stakeholders only when there are good and prudent reasons to do so. They should not be included when their involvement is not needed, impractical, or inappropriate.

Once the required participation is scoped, the next stage in the intervention process is to structure the MCDA evaluation model, which we present next.

STRUCTURING MCDA EVALUATION MODELS

There are three main tasks in structuring MCDA evaluation models: the *representation of objectives* in a value tree, the *definition of attributes* to measure the achievement of objectives, and the *identification of decision alternatives*. Below, we discuss each of these tasks and discuss the challenges that an analyst may encounter when undertaking them, as well as the tools/techniques that may be used to support their accomplishment.

Structuring Value Trees

The first step in building an MCDA evaluation model is always to represent the objectives that decision makers want to achieve (e.g., increase profitability, increase flexibility, reduce damage to the environment, and so on). In many multicriteria models, but particularly so in multi-attribute utility/value models [2], these objectives are organized as a value tree [1,30]. A value tree decomposes the overall objective of an evaluation into operational objectives, which can be more easily employed to assess the performances of decision alternatives. For example, Fig. 3 presents a value tree for evaluating different sites for building an industrial plant in Brazil. The client was concerned with the logistic costs associated with each site but also wanted to take into consideration the potential benefits from each site, such as accessibility to logistic

Figure 3. A value tree for selecting an industrial plant location.

systems (e.g., warehouses) and availability of skilled labor required for operating the plant.

Two approaches have classically been suggested for structuring a value tree [31,32]: top-down and bottom-up. The top-down approach is driven by the overall objective, which is then decomposed into objectives and the latter ones into sub-objectives, and so on. For example, if an analyst is structuring a value tree for the plant location problem described above, using a top-down approach, he/she would start with the overall objective (best location for the plant) and decompose it into logistic costs and benefits of the site. Each of these objectives could be decomposed even further, if required. The bottom-up approach is driven by the alternatives. In this case, the analyst would try to identify which attributes distinguish the alternatives and they would be included in the value tree. These attributes would then be grouped by their nature (e.g., in the plant location problem, all the attributes related to the potential benefits from a given site) and these groups could be further grouped upwards, composing the value tree.

There are compelling arguments that MCDA should employ a value-focused thinking approach for supporting decision making [6], as alternatives should be seen as mere means for organizations to achieve their fundamental and strategic objectives. This calls for a more top-down approach for structuring value trees. On the other hand, behavioral decision research has shown that individuals may struggle to think about their fundamental objectives [33], and may need

prompts from the analyst to reflect about the objectives prior to their explicit articulation. Behavioral research has also discovered that these two approaches (top-down and bottom-up) may generate value trees with different shapes [34], as values are “constructed” instead of merely extracted from decision makers’ minds [35]. Therefore, the choice of approach is clearly an important modeling decision that the analyst has to make.

Other possible tools for structuring a value tree involve the use of probes and grouping of ideas, such as Belton and Stewart’s CAUSE probes [1] and Parnell’s affinity diagrams [36]. Another set of tools for such purpose involves qualitative models that represent causality/influence between variables. Along these lines, Keeney [6] suggests the use of networks of means–ends objectives, where arrows represent the influence between a means and an end objective. Cognitive maps (illustrated in Fig. 1), a network of ideas connected by perceived influence and having a means–ends structure, have also been employed for structuring value trees [37–39] as discussed in Montibeller and Belton [40]. In a similar way, Merkhofer [41] suggests the use of qualitative influence diagrams to help the structuring of value trees. The main advantage of using these causality/influence tools is that they permit laddering-up toward the decision makers’ values, and laddering-down toward the attributes and decision alternatives, in a systematic and integrated way.

Objectives in a value tree must follow a set of properties that need to be checked when structuring it [1,2,6]. These properties are the following:

- *Essential*. They should consider all the essential organizational objectives involved in the decision.
- *Understandable*. They should have a clear meaning for all the members of the group involved in making the decision.
- *Operational*. It should be possible to measure the performance of decision alternatives against each of the fundamental objectives.
- *Nonredundant*. They should not measure the same concern twice.
- *Concise*. It should be the smallest number of objectives required for the analysis.
- *Preferentially independent*. If it is possible to measure the performance of decision alternatives on one objective disregarding their performance on all other objectives, then a simpler aggregation function can be used to aggregate partial performances.

Checking that these properties are observed in practice will usually, impact on the structure of a value tree. For example, a new objective may be included if the initial set does not cover all the essential issues in the evaluation. An objective may be removed, if it is not operational (e.g., if the information is considered as important but is unobtainable) or if it is redundant. Concerns about conciseness also can reduce the size of a value tree. Finally, if there are objectives that are preferentially dependent, the analyst may choose to restructure them to avoid using a complex aggregation function (for a detailed discussion on how to deal with preferential dependences, see Ref. 6).

Defining Attributes

For each objective placed at the bottom level of the value tree, an associated attribute or criterion should be specified. This attribute is a performance indicator employed to measure the impact of adopting each decision alternative on the organizational objective being pursued. There are two dimensions for classifying attributes in terms of: 1) the way it is measured; and 2) its alignment

with the objective being pursued [6,36,42]. We describe these two dimensions below.

The way the objective is measured: Direct or Indirect

- A *direct attribute* measures directly the degree of attaining the objective. For example, in Fig. 3, logistic costs have a direct attribute: the total logistic cost in US dollars.
- A *proxy attribute* measures indirectly the concern expressed by the objective, by assessing the degree of achievement of its associated objective. For instance, in the value tree shown in Fig. 3, the concern about having the planning permission granted is assessed by the number of months required for the processing of such permission.

The type of attribute: Natural or Constructed

- *Natural attributes* measure directly the concern expressed by the objective, are of general use and have a common interpretation. An example, in the value tree shown in Fig. 3, is to measure the logistic costs in US dollars.
- *Constructed attributes* measure directly, using indicators created specifically by the analyst, the concern expressed by the objective. In the plant location example, the availability of skilled labor (Fig. 3) is measured by a set of labels ranging from the best level ("wide availability of skilled labor from similar production plants in the region") to the worst one ("the plant will need to provide training to all its new employees").

Attributes can then be classified using these two dimensions; for example, a direct-natural attribute or a direct-constructed one. In terms of the way the objective is measured, whenever possible, it is usually better to use a direct attribute instead of a proxy one. If a direct attribute is not available, many times it is feasible to decompose an objective into subobjectives—with these subobjectives being assessed via direct

attributes—but avoiding excessive decomposition. In the same way, regarding the type of the attribute, a natural attribute is typically better than a constructed one, if the former is available and provides a clear way for decision makers to assess the alternatives. (See Refs 36, 42, and 43 for a comprehensive discussion on defining attributes and guidelines on how to develop suitable ones.)

Independently of its type, each attribute should possess five properties [42] if it were to be employed in a MCDA evaluation model:

- *Unambiguous.* The attribute should present a clear relationship between the impact of adopting a decision alternative and the description of such impact.
- *Comprehensive.* The attribute should cover the full range of possible consequences, if the decision alternatives were implemented.
- *Direct.* The attribute levels should describe as directly as possible the consequences of implementing a decision alternative.
- *Operational.* The information required by the attribute can be obtained in practice and it is possible to make value trade-offs between objectives [1,2].
- *Understandable.* Consequences and value trade-offs using the attribute can be clearly understood by the decision making group and communicated to other stakeholders.

Quantitative attributes tend to be less ambiguous than qualitative ones. A key point about comprehensiveness is that the upper and lower limits of the attribute are well-specified (maximum feasible and minimum acceptable, respectively) otherwise it would distort value trade-offs. Finally, it is critical that attributes are understandable, particularly if the analysis involves a group of decision makers and the modeling is conducted in a facilitated mode [44], such as in a decision conference [45].

Identifying Decision Alternatives

The other major task in structuring an MCDA evaluation model is the definition of

which decision alternatives will be assessed by the model. Traditionally, MCDA has taken an alternative-focused thinking perspective, where the set of options was assumed as given and stable [3]. However, the identification and creation of new alternatives is certainly one of the most important aspects of any MCDA intervention. No matter how careful and sophisticated the evaluation model is; if the decision alternatives under consideration are weak, it will lead to a poor choice [46].

An important aspect in structuring an MCDA model is that the decision alternatives should have the same nature (in the plant location example, for instance, all the alternatives are potential sites). If the analyst is careless about this aspect, it may be difficult to create a coherent value tree. There are several tools that may be employed in the creation/definition of decision alternatives, such as brainstorming techniques [47], cognitive mapping [18], dialog maps [22] among others.

Particularly useful tools are the ones, where decision alternatives are created from considering the decision makers' objectives [6] or stakeholders' values [48]. For example, the analyst can ask the decision makers to imagine options that could perform really well on a single objective. This process can be repeated for each of the fundamental objectives present in the value tree. Once the list of objectives is exhausted, the same procedure can be done for two objectives at once. Another way of creating a new option is by combining the existing alternatives, trying to maintain the best features of each alternative. Recently we have used a value-focused brainstorming using a cognitive map—which allowed eliciting, organizing, and displaying a large set of ideas from a client group—these ideas were then grouped as decision alternatives [39]. [For an extensive review of tools for creating alternatives see Keeney [6], Keller and Ho [49] and Parnell *et al.* [29].]

Although there is a natural tendency by decision makers to discard decision alternatives or options that may appear to generate some negative outcomes, any attempt at option evaluation should be contained at this stage. The assessment of alternatives should

Figure 4. An example of areas of interconnected options.

be left for the evaluation phase of the process and not intermingled with their generation.

Another aspect concerning the identification of decision alternatives is that there are instances where the alternatives are comprised by a large set of sub-options. There are some methods that can be used to structure complex decision alternatives. The strategy generation table proposed by Howard [50] is a simple way of creating decision strategies from the combination of options under several dimensions. Another tool is the analysis of interconnected decision areas (AIDA) technique that is a part of the strategic choice approach [23]. In this technique, the links between several “decision areas” are represented, each one with several options, with their compatibility explored, in order to generate a list of possible option portfolios. For example, in an intervention with a major international hotel company, we used AIDA to initially shape a strategic decision concerning how to tackle “cost of sale,” and produced a list of candidate interconnected strategic options, grouped in three areas (*distribution, timing launch, and scope level*). This is shown in Fig. 4, where the links between

specific options represent incompatible combinations.

AN INTERVENTION FRAMEWORK

The techniques for multicriteria evaluations are already well-established in the literature. However, there has been much less investment in the development of techniques to support the structuring stages of MCDA interventions. We have reviewed both the mainstream problem structuring and MCDA literatures, and identified a number of modeling tools, which can be used to support problem structuring in MCDA interventions. Perhaps, more importantly, our foregoing discussion should have made clear to the reader of the important role that problem structuring plays in MCDA interventions.

In Fig. 5, we suggest a framework for conducting MCDA interventions, in which the role of problem structuring is made explicit. In Phase 1, the analyst structures the problem situation, helping the client to arrive at an agreed problem definition, and designs a decision process with the appropriate level of participation. Once this phase is finished,

Figure 5. A framework for structuring MCDA models.

the analyst then can start Phase 2, the structuring of an MCDA model, which consists of eliciting and distinguishing means and fundamental objectives, structuring a value tree, developing attributes and identifying decision alternatives. With this second phase completed, the analyst can finally proceed to undertake Phase 3, modelling preferences and the evaluation of decision alternatives. The natural flow of phases is indicated with black arrows in Fig. 5, but notice that the process is not linear and can cycle back to earlier phases (grey arrows): back from Phase 2 to 1, if the structuring of the MCDA model changes the definition of the problem or the scope of stakeholders' participation; back from Phase 3 to 2, if modelling of preferences or the assessment of alternatives changes the structure of the MCDA model; and back from Phase 3 to 1, if modelling of preferences or the assessment of alternatives changes either the definition of the problem or the participation required. Table 1 contains a list of useful tools for supporting the different activities within each of the structuring phases of an MCDA intervention.

CONCLUSIONS AND DIRECTIONS FOR RESEARCH

While decision analysts have recognized for a long time the importance of problem structuring for successful MCDA interventions, most of them have relied on ad hoc practices for structuring the decision problem. The main aim of this chapter has been to provide a review of tools that can help this pre-MCDA evaluation phase of problem structuring. Furthermore, we have also reviewed the main tasks involved in building an MCDA evaluation model per se, while attempting to provide a more integrated view by relating these tasks with the problem-structuring literature.

As discussed in this chapter, there are a number of problem-structuring tools available to help decision analysts deploy effective MCDA interventions. However, our discussion should have also made clear that when the client comprises a group of managers, mastering the tools will not be sufficient. The analyst will also need skills for facilitating the group processes associated with

Table 1. Tasks and Tools for Structuring MCDA Models

Phase 1: Problem Structuring		
Activity	Task	Supporting Tools and Useful References
Defining the Problem	Capture the different understandings about the multicriteria problem and facilitate a definition of the problem that is shared by the client (or client group).	• Cognitive mapping [18,19] • Dialog mapping [22] • Soft systems methodology [20,21] • Strategic choice approach [23] • Group model building [24] • Decision framing [6]
Scoping Participation	Determine the type and level of participation of different stakeholders required for the intervention.	• Power-interest grid; star diagrams and stakeholder influence diagrams [17] • Stakeholder-issue interrelation diagram and problem-frame stakeholder maps [28]
Phase 2: Structuring the MCDA Evaluation Model		
Activity	Task	Supporting Tools and Useful References
Structuring Value Trees	Organize the objectives to be considered in the evaluation as a hierarchy.	• Top-down or bottom-up approaches [31] • Checklist and grouping of ideas [1,36] • Means-ends objective networks [6] • Cognitive maps [37–39] • Qualitative influence diagrams [41] • Checklist of properties for a value tree [1,6]
Defining Attributes	Specify, for each bottom level objective in the value tree, an associated attribute.	• Keeney's and Gregory's [42] decision model for selecting attributes and Parnell's [36] preference ranking for selecting attributes • Kirkwood's [43] classification of attributes and guidelines for their development • Checklist of properties for an attribute [6]
Identifying Decision Alternatives	Define/identify/create decision alternatives to be assessed by the MCDA model.	• Brainstorming [47] • Laddering-down in a cognitive map [18,19] • Dialog maps [22] • Focus on the objectives to be achieved [6,49] • Ideation techniques [29] • Strategy tables [50] • Analysis of interconnected decision areas [23]

defining the problem, which are significantly influenced by the power and interests of the managers in that group [16,44].

It worth noting that the chapter has focused on modeling decision making with multiple objectives. Frequently, however, key uncertainties are present and should also be represented. Useful tools for modeling

decision making under uncertainty are influence diagrams [51] and decision trees [52]. A good introduction to this type of modeling is provided by Clemen and Reilly [53] and Kirkwood [54].

We believe that problem structuring for MCDA is a rich field of research, where the focus can be not about developing and testing

suitable problem structuring tools, as well as about the study of facilitated modeling in this intervention context. We thus suggest some directions for further research:

- *Development of Problem-Structuring Methods.* While the field of problem-structuring methods (PSMs) is already well-established in management science, more research could be conducted on tools that could be tailored specifically for MCDA interventions.
- *Integrated Use of PSMs.* The use of standard PSMs with MCDA requires transitions from a problem-structuring model to a multicriteria decision analysis model, which may prove challenging [40]. Consequently, a direction of research is the development of methods that could provide a seamless transition. The reasoning maps method, suggested by Montibeller *et al.* [55], and the use of means objectives to assess the performance of decision alternatives on fundamental objectives, suggested by Butler *et al.* [56] are examples of research in this direction.
- *Tools for Supporting Structuring MCDA Tasks.* The paper reviewed some tools that could be employed for structuring value trees, defining attributes and identifying decision alternatives. The development of new tools is, however, still a potentially area of research—particularly if it were based more on psychological aspects [e.g., how to spark off creativity when creating alternatives; how to identify/display complex options to a group of decision makers, such as the approach proposed by Montibeller *et al.* [39]].

To summarize, this chapter provided an overview of the phases and tasks involved in structuring an MCDA evaluation model within an intervention, from defining the problem and identifying key stakeholders to building the MCDA model itself. Problem structuring is a fundamental and challenging task for any MCDA intervention; thus, we hope this chapter may be of help to decision analysts involved in such interventions

and may also serve as a useful resource for researchers interested in this field.

INTRODUCTION

The problem of securing a supply of raw materials, components, subassemblies, and finished goods at a stable and known price is not a new one. It is one of the main difficulties of every industrial (and not only industrial) organization. This problem is becoming even more acute due to the common practice of outsourcing and decentralization. In a decentralized environment, independent entities, each with its own plans and objectives, are purchasing raw materials, components, subassemblies, and finished products from each other. Clearly, each entity is interested in ensuring that it obtains the right quantity of inputs, of the right quality, at the right time, while minimizing cost. Coordinating the supply chain is complex and difficult. Some of the main reasons are as follows: players in the supply chain are facing uncertainties regarding the supply and demand; production lead times are long, and thus procurement managers are forced to place orders long before they observe the actual demand; their decisions are based on forecasts that are usually not accurate; economies of scale often force decision makers to place large orders and thus prevent them from observing the actual demand and continuously adjusting to the changing market conditions. Finally, one of the most important difficulties is that each entity in the supply chain is interested in maximizing its own utility but not necessarily the utility of the entire supply chain.

The issue of designing supply contracts is not new, but today it has become a crucial element of the procurement function. This is

due to the decentralization of companies and the fact that outsourcing of services and products is by now the common mode of operation. This is in contrast to the not-so-distant past, in which industrial companies were vertically integrated and coordinating the supply channel was much easier. In such environments, a single decision maker made the decisions for all of the involved entities of the organization, thereby optimizing the performance of the entire organization and not just the performance of each of the entities as a “stand-alone” unit.

Usually, supply contracts are part of the process of procuring goods in manufacturing and retail industries. More recently, it has been observed that such contracts are also an important part of health-care delivery, especially the global health-care delivery system. The reason is that many of the patients live in low-income countries and are too poor to pay the full price of expensive medications. In such environments, where markets do not exist, manufacturers are reluctant to invest in research and development of new drugs and in production capacity. We believe, as we describe in what follows, that supply contracts are an important tool to ensure availability and affordability of drugs.

In this article, we concentrate on contracts that deal with risk and uncertainty: in most cases, we deal with the uncertainty in the demand for goods and services. But, contracts are also used in other cases, especially in cases in which there is no uncertainty. A good example is quantity discount contracts. Quantity discount contracts can be applied in a deterministic environment. The main idea is to induce buyers and sellers to produce and purchase quantities that generate operational efficiencies. Such contracts are common when economies of scale are presented. Transportation systems are a good example. Sellers offer price discount to induce buyers to purchase larger quantities than those that they would have purchased otherwise. By doing so, sellers are able to ship full truck loads and reduce the per unit ship-

ping cost. The interested reader is referred to the seminal paper by Rosenblatt and Lee [1]. A description and classification of quantity discount contracts is in Munson and Rosenblatt [2].

For obvious reasons, we are unable to discuss all types of procurement contracts here. We describe some of the most important contracts in short. A more inclusive and detailed review can be found in Cachon [3]. The section titled “Contracts in Supply Chains” in this encyclopedia provides a very good discussion on the many different aspects of contracts.

FLEXIBILITY AND STABILITY

As mentioned above, the main objective of supply contracts is to ensure the availability of the right quantity and quality of goods and services at the right time and at the lowest possible cost. In most of the contracts that we discuss here, one of the main drivers of cost is risk. More specifically, all supply contracts are concerned with the allocation of risk between the different entities in the supply chain. (Here referred to as *suppliers and buyers*). The question that all supply contracts are addressing is the question of who should bear the risk of producing ahead of time and keeping raw materials, components, and finished goods. Suppliers like a stable environment in which all orders are

firm, and once a buyer places an order the buyer must take and pay for the goods. On the other hand, buyers like the flexibility to place orders and then change these orders as they learn more about the actual demand. We argue that in many cases the right balance between stability and flexibility maximizes the utility of the supply chain and can ensure a “win-win” situation.

A good example that illustrates this phenomenon was provided long ago by Blois [4], as shown in Table 1.

One can see how the monthly order changes as we approach the delivery time. For example, in March, the scheduled delivery for December was 22,700 units, but in June the scheduled quantity was reduced to 14,500. It is not difficult to imagine the difficulties that the supplier is facing by such big changes in the orders and the resulting additional cost. Thus, the role of a supply contract is not only to ensure demand (for the supplier), supply (for the buyer), and to improve the production planning process but also to create a flexible environment in which buyers can adjust to the changing conditions of the market. At the same time, it is necessary to keep the suppliers’ environment stable without imposing too much risk and costs on the suppliers.

To further illustrate the trade-off between stability and flexibility, we use the graph (Fig. 1) provided by Rietveld Hans [5].

Table 1. Company B’s Schedules of its Requirements from Company A

Schedule Issued on:		12/1/60	29/3/60	29/6/60	18/7/60	23/11/60
Delivery Required in:						
July ^a	1960	10,000				
August ^b		25,000		16,800		
September		20,000		13,500		
October ^b			28,400	18,100		
November			22,700	14,500		
December			22,700	14,500		5400
January ^b	1961				12,900	5700
February					10,300	5400
March					10,300	5400
April						5700
May ^b						5400
June						6200

^aHoliday month—only two weeks production.

^bFive week month.

Figure 1. Production capacity confirmed orders and actual deliveries.

This graph illustrates several key issues crucial to the design of supply contracts. Despite the high demand for Malaria drugs (300–500 M instances per year) and despite the available capacity (100 M units), the manufacturer does not use all of its capacity. While there are several reasons for this, one of the main reasons mentioned by the manufacturer (Novartis) is the uncertainty in the delivery quantity. In 2005, a large quantity was ordered but only a relatively small quantity was picked and delivered. The reason is that orders are placed long in advance because of the long production lead time. When delivery time arrives, the market conditions may be different, forcing the buyers to change their previously made orders, resulting in a large loss to the manufacturer. This graph illustrates the general issue of balancing flexibility and stability. Buyers would like the flexibility to change previously made orders to better adjust to changing market conditions. Suppliers, on the other hand, would like to operate in a more stable environment in which the flexibility to change previously made orders is

limited. If the “right” balance between flexibility and stability is not achieved, sellers (buyers) may produce (purchase) less than the desired quantity and reduce their exposure to risk. How to balance flexibility and stability and allocate the risk between buyers and manufacturers is exactly the role of the procurement contracts that are discussed in this article.

MINIMUM COMMITMENTS

The total-minimum-quantity contract addresses two different issues as follows; (i) It gives the buyer some flexibility to change orders and to adjust to changing market conditions, but at the same time it limits the buyer’s flexibility to change order sizes drastically, which helps in avoiding increases in the production cost for the supplier. (ii) It provides incentives to suppliers to build capacity even when the demand is uncertain, and it shares the risk of investing in capacity between the supplier and the buyers.

Bassok and Anupindi [6] use the framework of a multiperiod news-vendor model,

which assumes that the periodical (month, week) demand is unknown but that a forecaster is able to provide a probability distribution of the demand. Also, in this model, it is assumed that the demand is stationary and independent—that is, the demand in each period follows the same probability distribution and demands across periods are not correlated. The authors consider a finite horizon problem that is a problem with a limited number of periods (for example, one year). The optimal solution for this problem is well known: every period has a critical number S_t (the “base stock”), so that in period t it is optimal to raise the available inventory (on-hand inventory) and order up to the base stock. The reader will notice that in such a model the buyer firm has all the flexibility to order any quantity it wishes, which means that the supplier environment is far from stable. This “order-up-to” policy obviously minimizes the buyer’s cost, but just as obviously it ignores its effects on the supplier’s cost.

To mitigate the negative effects of demand uncertainty on the supplier’s performance, the buyer is required to announce its minimum purchasing quantity for the entire horizon. For making the minimum purchasing commitment, the supplier offers a discounted purchasing price per unit. By making the “minimum commitment,” the buyer limits its own flexibility. If, for example, the total demand during the horizon turns out to be lower than the total commitment, then the buyer must still take delivery of the committed quantity and pay for it. If the total demand turns out to be higher than the total commitment, then the buyer will have to purchase the difference between the total demand and the total commitment at a higher price. On the other hand, the buyer still has the flexibility to place periodical orders of any size, as long as the sum of the periodical orders is not greater than the “minimum commitment.”

The supplier also benefits from such a contract because it knows with certainty that during the horizon it will have a buyer for the committed minimum quantity, which means the firm can plan its production in an efficient way.

The authors concentrate on the effects of the minimum commitment contract on the buyer’s performance. They are mainly interested in determining the optimal purchasing policy of the buyer assuming that it makes a minimum commitment to purchase K units during the horizon. They prove that the optimal purchasing policy of the buyer has a very simple structure and that it is very easy to calculate the optimal periodical purchasing quantity. The crux of the optimal policy is as follows. At the beginning of every period, if the sum of the buyer’s earlier purchases is still smaller than the minimum commitment, then it is optimal for the buyer to raise its inventory to the base stock S^M , where S^M is the optimal base stock for a single-period news-vendor problem assuming that the purchasing cost is equal to zero. If, at the beginning of a period, the sum of earlier purchases is larger than the minimum commitment, then the buyer needs to solve a standard multiperiod problem without any commitments.

By following such a simple policy, the buyer minimizes its cost. Clearly, the supplier is interested in the buyer making a large commitment and, to encourage the buyer to do so, the supplier is willing to provide the buyer with a per-unit discount. The effect of the commitment on the buyer’s cost is illustrated by the following graph (Fig. 2) [6].

The graph shows us that as the total commitment is increasing the total saving is decreasing. This is expected because the larger the commitment, the larger is the buyer’s risk. The graph is useful in determining the optimal commitments. For example, it is better for the buyer to commit for 750 units with a 5% discount than for 900 units with 10% discount.

The minimum-commitment contract can be used to encourage companies to build production capacity. This is especially true in environments in which there are no markets for the produced goods. A good example is the sub-Saharan countries, in which most of the population is unable to purchase life-saving drugs. Private and public organizations are willing to subsidize the drugs and to ensure that they are available and affordable to the needy, but usually the size and the duration

Figure 2. Effect of price discount.

of subsidy is not well defined and is uncertain. As a result, drug manufacturers are unwilling to take the risk and build capacity to produce drugs for low-income countries.

To solve this problem, several researchers have suggested that the private and public organizations make clear and well-defined commitments to subsidize certain drugs (for example, malaria drugs). The total amount and the duration of such a commitment should be advertised ahead of time and ensured by a third party. Finally, a neutral organization (e.g., the World Health Organization) will have to provide a list of drugs that should be subsidized by the private and public organizations. By providing a total minimum-quantity commitment, the private and public donors are able to mimic market conditions and provide a more stable environment for the manufacturers, who will now be certain that they will sell at least the minimum-commitment quantity. Clearly, this is an incentive for pharmaceutical companies to enter the market and invest in production capacity.

PERIODICAL COMMITMENTS AND FLEXIBILITY

The total-minimum-quantity commitment solves several problems, especially ensuring that suppliers will sell at least a minimum quantity during the horizon. But it does not deal with the changing periodical orders. Buyers still have the flexibility to change their previously made orders to better meet the actual demand. It is clear that buyers would like the flexibility to change

previously made orders at any time, but it is also evident that suppliers would like to limit this flexibility, ensure stability, and force the buyer to commit and make firm periodical orders. Bassok *et al.* [7], Anupindi and Bassok [8], and Tsay and Lovejoy [9] all address the issue of balancing flexibility and stability.

Common to these studies are several concepts. The buyer, before the horizon starts, makes periodical commitments $q_{0,1}, q_{0,2}, \dots, q_{0,N}$, where $q_{i,j}$ is the commitment made at period i for period j . At the beginning of period 1, the buyer may change the order quantity to be delivered during this period $q_{1,1}$ to be: $(1 - l_0)q_{0,1} \leq q_{1,1} \leq (1 + u_0)q_{0,1}$. Thus, the buyer has the downward flexibility of l_0 and the upward flexibility of u_0 . Thus, the buyer does not have the infinite flexibility to purchase any quantity it wishes but rather must stay within the limits determined by its original commitment and the downward and upward flexibility limits. In addition, the buyer may change its future commitment in a restricted way

$$\begin{aligned} (1 - l_1)q_{0,2} &\leq q_{1,2} \leq (1 + u_1)q_{0,2} \\ (1 - l_2)q_{0,3} &\leq q_{1,3} \leq (1 + u_2)q_{0,3} \\ (1 - l_{N-1})q_{0,N} &\leq q_{1,N} \leq (1 + u_{N-1})q_{0,N}, \end{aligned}$$

where $l_1 \leq l_2 \leq \dots \leq l_{N-1}$ and $u_1 \leq u_2 \leq \dots \leq u_{N-1}$.

Anupindi and Bassok [8] graphically describe the dynamics of this contract in the following way (Fig. 3):

The current period is represented by a diamond and the future periods by a rectangle. Suppose the commitment for period 3

Figure 3. The dynamics of the periodical commitment and flexibility contracts.

made in period 0 was 120 units. In period 1, this commitment can be adjusted upward or downward by 20%. Thus, in period 1, the buyer can adjust the commitment in period 3 to any quantity between [96,144]. Suppose the buyer decides, at the beginning of period 1, to commit to purchase 110 units. In period 2, the commitment made for period 3 can be adjusted upward or downward only by 10%—that is, the adjusted commitment could be between [99,121]. Now let us say that the buyer chooses 100 units. In period 3, the buyer has 5% upward and downward flexibility and can purchase any quantity between [95,100].

This process repeats itself every period. The idea is to enable buyers to change their previously made commitments in a restricted way. When the time between making a new commitment (period i) and the actual delivery time (period j) is short, the flexibility is very limited. But when the time between making the commitment and the actual delivery is long, the flexibility is large. This is achieved by l_{j-i} and u_{j-i} increasing with $j - i$, and the number of updates that the buyer is able to make. The reason behind the structure of flexibility contract downward and upward constraints is that changes in the order quantity, with a very short notice, are costly for the supplier, while changes with a long notice

are much cheaper, and in this case changes in the previously made commitment can be relatively large.

All three studies aim to identify the optimal initial periodical commitments and the optimal periodical updates. Determining the optimal policy is very difficult, and all studies resort to approximation and heuristic. Basok *et al.* [7] develop a lower and upper bound on the total costs. The lower bound is achieved by assuming that the flexibility is very large—that is, assuming that changing previously made commitments is not limited. In this case, the structure of the optimal policy is well known: there are critical numbers (base stocks) $S_1, S_2, \dots, S_N$ so that at the beginning of each period it is optimal to raise the inventory up to the base stock. The idea behind the upper bound on the total cost is somewhat more involved. The upper bound policy is a feasible policy (changes in the commitment quantities are limited and satisfy the flexibility constraints). The changes are made so that the probability of reaching the base stocks $S_1, S_2, \dots, S_N$ is maximized. The authors show that the gap between the upper and lower bounds is not too large. For example, when the coefficient of variation of the demand is smaller than 0.5, the maximum gap is only 7% (assuming upper and lower flexibility of only 5%). Since the gap is

Figure 4. Breakeven purchasing cost versus flexibility under stationary demands ($c = 40, h = 1, p = 100, T = 12, \mu = 1000$), where c is the purchasing cost per unit, h is the holding cost per unit, p is the shortage cost per unit, μ is the mean demand, and σ is the standard deviation of the demand. [Source: Bassok *et al.* [7].]

small, the authors use the upper bound to calculate the optimal initial commitments and the updates of the periodical commitments.

The ability to determine close-to-optimal commitments and then to update them provides a very important tool in the negotiation process between buyers and suppliers. The suppliers may provide different levels of upward and downward flexibility, but for a higher flexibility the supplier demands a higher per-unit cost. This relationship is illustrated in the following graph (Fig. 4).

The reader can see that when the coefficient of variation is 0.75, the buyer should pay no more than 41.7 per unit for 0.2 upward and downward flexibility.

FIXED-DELIVERY CONTRACT

A contract that has similar features to the periodical orders and flexibility is presented by Moynzadeh and Nahmias [10]. These authors consider a fixed-delivery contract, and they assume a finite-horizon model with backorders and independent and stationary demand. The buyer is committed to purchasing the same quantity Q at a cost per unit of c in every period. The buyers have upward flexibility to order more than Q , but they have to pay a premium for the additional quantity, and the cost per unit is c_H (where $c_H > c$). In addition, every time the buyer deviates from the committed quantity Q , it must pay a fixed cost K . The fixed-delivery

contract captures the fact that in certain industries it is very costly to change the production quantity. Thus, suppliers prefer to produce the same quantity in every period. On the other hand, the buyer prefers to have flexibility to adapt to the uncertain demand and update the fixed-delivery quantity. The fixed-delivery contract offers limited flexibility because the buyer may purchase more than the fixed-delivery quantity but not less.

At first glance, it seems that the fixed-delivery contract is mostly advantageous to the supplier, who is able to reduce the variability in the orders. However, this observation is misleading. The benefit to the buyer depends upon the price discount that the supplier offers, c , and the premium price c_H . There is always a large-enough discount so that the buyer also benefits from the fixed discount contract.

BACKUP CONTRACTS

Eppen and Iyer [11] present a backup contract that has some of the flavors of the commitment-and-flexibility contract presented above. They consider a model that is very common in the apparel industry, especially between the manufacturer and a catalog (retailer). They suggest a two-period model. Before the first period, the buyer must make a purchasing decision, q , for the two periods. Yet, they take delivery of

only $Q(1 - \beta)$ units. Once they observe the demand, at the first period, they take a delivery of up to $Q\beta$ units, but not more than that. While the cost per unit is c , the cost per unit that the buyer does not take (at the most $Q\beta$ unit) is b . This contract is similar to the periodical-commitment-with-flexibility contract.

Notice that the buyer (catalog) makes a commitment to purchase Q units. The upward flexibility is zero and the downward flexibility is β . The main differences between the two contracts are (i) the periodical-commitment-with-flexibility contract is a multiperiod contract, while the backup contract is limited to only two periods; (ii) in the periodical-commitment-with-flexibility contract, the demands in the different periods are assumed to be independent, while the demands in the backup contracts are assumed to be correlated; and (iii) in the backup contract there is an explicit penalty per unit, b , for not purchasing units that were actually ordered. In the periodical-commitment-with-flexibility contract, the cost of flexibility is captured by the cost per unit of the product—the greater the flexibility, the higher is the cost per unit. But there is no explicit cost for units that were ordered but not purchased.

As the value of b (the penalty per unit for not purchasing the committed quantity) increases, the value of the backup contract decreases. This is quite intuitive because when b is very large, the buyer will tend to purchase all of the committed quantity and thus the backup option has zero value. Similarly, as l increases and the buyer has the opportunity to purchase a smaller fraction of the commitment, the total cost for the buyer increases.

Perhaps more interesting is the fact that the backup contracts provide the buyer with an incentive to commit to a larger quantity than the quantity that it would have purchased without the backup contract. This is a very important observation. The backup contract provides the buyer with flexibility and thus reduces the buyer's risk and induces the buyer to commit for more units. The supplier, who assumes a larger share of the risk benefits by selling a larger quantity.

The magnitude in this difference can be large, and the authors provide an example in which the committed quantity in the backup contract is larger by 63% than the purchasing quantity without a buyback agreement.

It is interesting to observe that for certain parameters both the supplier and the buyer benefit from the backup contract. Thus, one can ask what the parameters of the backup contracts that minimize the sum of the cost of both the buyer and the supplier are, and when is it possible to coordinate the channel. We will address this issue shortly.

OPTIONS CONTRACTS

The main idea of the above contracts is that they provide the buyer with flexibility to adjust to changing market conditions and, at the same time, they provide the supplier with information that helps the supplier to create a stable environment and plan its production and reduce cost better. All of the above contracts can be viewed as special cases of the following option contract. In a two-period option contract, the buyer makes periodical orders Q_1 and Q_2 , at a price c per unit. These orders are firm orders and cannot be changed. In addition, the buyer purchases M options, at the option price c_o per unit. These options may be exercised at the second period at the exercise price c_e .

As is the case in all of the previous contracts, the buyer would like to have the flexibility to change its previously made orders, while the supplier would like to limit the flexibility and encourage the buyer to limit the changes to the previously made orders. Clearly, if $c_o + c_e$ is large enough, then the buyer will tend not to purchase any options and will have zero flexibility. On the other hand, if $c_o + c_e = c$, the buyer will not make any commitment for the second period and will only purchase options. Choosing the right levels of c_o and c_e makes it possible to strike a balance between the interests of the buyer and the supplier and perhaps even to reduce (increase) the cost (profits) of both. The reader may notice that the option contract is a generalization of the two-period flexibility contract and the backup contracts.

Table 2. Special Cases

General model	Q_1	Q_2	M	c_1	c_2	c_o	c_e
Backup agreement	$Q(1 - \beta)$	0	$Q\beta$	c		b	$C - b$
QF contract	$\tilde{Q}_1$	$(1 - \alpha_d)\tilde{Q}_2$	$(\alpha_d + \alpha_u)\tilde{Q}_2$	c	c	0	c

[Source: Barnes-Schuster *et al.* [12].]

The table below (Table 2) demonstrates that these contracts are special cases of the option contract.

It is clear, for example, that the backup contract is a special case of the option contract. In both contracts, the buyer commits to purchase a certain quantity. The actions in the second period are different. In the backup contract, the buyer does not commit to any quantity, while in the options contract the buyer may commit to any quantity, Q_2 . Second, the backup contract limits the number of options that the buyer may purchase; it is a function of the buyer's first-period commitment. On the other hand, the option contract provides the buyer with the flexibility to purchase any number of options.

Barnes-Schuster *et al.* [12] provide a detailed two-period option model. In addition to studying the behavior of the buyer, they also study in detail the behavior of the supplier and the entire channel. The sequence of action assumed in this study is provided below (Fig. 5):

This model assumes that the supplier may produce ahead of time up to $Q_1 + Q_2 + M$ units. By producing ahead of time with a long production lead time, the buyer utilizes a less costly technology, but the supplier incurs

holding cost, and perhaps more importantly it assumes the risk of having, at the end of the last period, obsolete inventory. Alternatively, the supplier can produce a smaller quantity, wait until the buyer decides how many options to exercise, and only then produce the goods. In this case, the production cost per unit is high due to the short production lead time. Clearly, such a policy seems to be costly due to the high production cost. Yet, it reduces the inventory holding cost and the risk of obsolete goods that were produced but cannot be sold.

Such contracts are common practice in the apparel industry. The difficulty in this industry is the long lead time in producing the raw material. The knitting and weaving, dying and printing operations have a long production lead time. The sewing itself can be done relatively quickly. Suppliers (manufacturers), in order to minimize risk, tend to keep low inventories of raw materials—just enough to produce the ordered quantity. This results in one production run that is performed long before the season start, which creates a situation in which it is retailers who are unable to place a second order during the season when they have better information

**Figure 5.** A timeline of buyer-supplier decisions.

about the actual demand. The option contract reduces the supplier's risk of keeping raw materials because the buyer shares this risk by paying the option price. By keeping raw materials in stock, the suppliers are able to produce quickly and, if necessary, to produce and deliver during the season. Thus, it provides the buyer with the needed flexibility.

This detailed model not only determines the optimal commitments, the number of options, and the options and exercise prices, but it is also instrumental in identifying the optimal production policy for the supplier—in other words, how much should the supplier produce ahead of time at a low production cost, and which fraction of the total should be produced at a later time only and at a higher production cost. The fact that it is possible to consider that the supplier production policy leads the authors to ask whether it is possible to coordinate the channel. We remind the reader that we say that the channel is coordinated when the sum of the costs (profits) of the supplier and the buyer are the same as the costs (profits) in a centralized system with a single decision maker who optimizes the performance of the entire supply chain. In addition, if it is possible to coordinate the channel, it will be interesting to find out whether it is possible to allocate the cost (profit) between the buyer and the supplier in any arbitrary way. If the answer to both questions is positive, then it is possible to find options and exercise prices so that both players improve their costs (profits) as compared with other contracts. A detailed discussion of channel coordination is found in the article titled *Supply Chain Coordination* in this encyclopedia.

It turns out that in general it is impossible to coordinate the channel with linear prices. There are some instances (depending upon the cost parameters) that enable the coordination of the channel. But in these cases the prices are not individually rational for the supplier. Even return policies that are known to coordinate the channel in many environments fail to coordinate the channel in this case. One of the main difficulties in coordinating the channel is the fact that production cost is not linear. To see this point,

consider a buyer that purchases M options. The supplier may produce ahead of time, at a low cost, some fraction of the M options, then wait until a later time to see the actual number of options that are exercised and, finally, if necessary, produce an additional quantity at a higher cost. Thus, the actual production cost is not linear. The option contract assumes that the supplier charges the buyer a linear price. As a result, the number of options bought and exercised, assuming an option contract, is not the same as in the centralized system. Thus, in general, options contracts do not coordinate the channel. More on option contracts can be found in Refs 13 and 14.

CONCLUSIONS

The main issue in designing supply contracts is to ensure supplies and goods at the right quantity, quality, time, and cost. The tension is always between the wishes of buyers to have as much flexibility as possible and suppliers, who benefit from a stable environment and early firm commitments. Balancing this with flexibility can be done in different ways, but in all the cases stability and flexibility have real costs that can be evaluated, quantified, and used to calculate acceptable solutions for suppliers as well as buyers.

PRODUCT/SERVICE DESIGN COLLABORATION: MANAGING THE PRODUCT LIFE CYCLE¹

M. ERIC JOHNSON
Tuck School of Business,
Dartmouth College,
Hanover, New Hampshire

INTRODUCTION

Revenue growth in any industry requires a steady stream of innovative products and services. Without new market offerings, firms quickly find themselves left behind as customers defect to innovative competitors. This is particularly true for short-life products, like apparel or smart phones, where product life cycles have shrunk, driving the need for even more new products. Services are a little different—without innovation hotels become unattractive commodities and theme parks grow stale. Yet developing and bringing new offerings to market is becoming increasingly complex. Products with many components form challenging coupled problems, requiring substantial design iteration [4]. The driving forces of outsourcing and globalization have fragmented supply chains, with design activities now spread across firms and locations [1]. Product designers, marketers, and manufacturers are no longer in the same building or organization. More likely, they are spread over several continents in organizations with different cultures, languages, and business objectives. Once immune from such pressures, services are no longer local businesses and are also becoming more fragmented and global. The result is even greater challenges in managing the design process.

For example, brands like Hewlett-Packard, Dell, or Levi's used to do it all—operating their own US production plants along with their core design and marketing activities. Now, these firms have closed the production plants that once dotted the United States and outsourced much of that production and even design. Likewise, service help desks have moved to India and product recovery to China. While such outsourcing has had positive effects on product cost structures and asset management, it has dramatically increased supply chain complexity. Supply chains now span the globe with many hands touching a garment or electronic product before it reaches the consumer. Without solid processes and good communication, coordination failures can quickly snowball. When this happens, services fail to meet customer expectations or products arrive too late for the intended season, missing market share opportunities or requiring deep markdowns to liquidate the inventory before the next season arrives.

To be successful with such fragmented supply chains, firms must find ways to leverage their global partnerships through better design collaboration. Product design collaboration is a key element of product life cycle management [5,6]. Many think of product design as something that happens once, early in the development of a product, and then is over. However, design decisions [7] and the need to collaborate around the design continue throughout the life of a product. And the benefits of strong collaborative processes are not limited to short-life products. For long-life products, such as construction equipment or aircraft, products require ongoing maintenance and service enhancements to provide high lifetime value to end customers. Again, collaboration is critical for improving products, introducing new services, driving down cycle times, reducing both supply chain costs and the long-term cost of ownership for customers.

This article examines how firms in different businesses use collaborative approaches

¹This article substantially relies on the work of Johnson [1,2], and Kopczak and Johnson [3].

Figure 1. Stages of the product life cycle.

throughout the product life cycle. The life cycle of a product follows multiple stages (Fig. 1), including everything from the initial idea to the final recovery and recycling.

Collaboration around the definition of the product or service can happen at every stage of life. It is important to note that collaboration is not negotiation, nor is it simply learning from a partner. True product collaboration involves reliance on the unique expertise and experience of suppliers, partners, and customers, and delegation of a share of meaningful decision making. As companies implement collaborative software tools with their partners, the concurrent changes in technology, structure, work process, and organization depend on and impact trust within the supply chain. Thus, success in collaboration is as much about processes and technology as it is about organizational design and trust.

Often specific information technology tools are employed to enable collaboration at each stage. Sometimes those software products are focused on very specific problems facing particular industry issues (for example, storyboarding in apparel or engineering changes in computer hardware). Recently, many large software vendors (for example, Oracle and

SAP) have begun consolidating many of these point solutions into a suite of integrated tools that addresses the whole product life cycle. The focus of this article is the underlying challenges of life cycle management and the potential value of collaboration. To illustrate collaborative approaches, this article will present the key concepts of collaboration within the context of three case studies from different industries.

MANAGING PRODUCT CONTENT—THE ELECTRONICS INDUSTRY

Product collaboration in the electronics industry grew out of the need to better manage and synchronize product content information across the supply chain. Product content information is all of the data needed to manufacture a product to the correct specifications and at the most recent release. This includes such details as the bill of materials (BOM), drawings, lists of approved manufacturers for each component, and the process information needed by manufacturing to build and test a quality product. Typically, the BOM is a list of parts and subassemblies that make up the product, arranged in a

hierarchical format. For example, at the highest level is the final product. The next level of the BOM consists of major subassemblies followed by the smaller assemblies and components that make up each subassembly. Accuracy of this information is critical for procurement to buy the correct parts and manufacturing to assemble the right product.

As supply chains fragment into a string of outsourced services coordinated by virtual manufacturers, the need for content synchronization grows. In firms where marketing, R&D, procurement, manufacturing, and distribution are co-located on single site, synchronization (and collaboration) can occur without good information management. In the early idea stages of a product, designers can propose ideas over coffee with colleagues in marketing and manufacturing. During a new product introduction, manufacturing engineers can stroll down to R&D any time questions arise. When changes occur in the design or sourcing of material, development and procurement specialists can run downstairs to the shop floor to be sure the changes are understood and will not create production conflicts.

However, few electronic companies have such control over their products. More likely, designers are in Boston, assembly is outsourced to Southeast Asia, components are procured from an array of global firms, and distribution is handled by third-party providers who not only fulfill orders but also customize the products for unique customer needs (Fig. 2). For original equipment manufacturers (OEM), product licensees each have their own unique design needs, marketing

issues, and distribution requirements. Each partner in the chain must, at a minimum, have accurate, current product content information. Traditionally, critical product content information was often transferred in a hodgepodge of drawings, CAD files, spreadsheets, and text documents. Poorly managed product content information is a key source of supply chain headaches—particularly during new product introduction. One slip in the information relay race and products are assembled with the wrong parts or orders pile up waiting for components.

For example, consider a typical blunder made by an OEM who designed and marketed an electronic product. In a move to improve the functionality of the product, designers at the OEM made a routine change in one key specialized component that was supplied from their component distributor. The procurement managers at both the OEM and the manufacturing partner made the change and started ordering small quantities of the new component from the distributor. However, because the product content data was not integrated with the procurement systems, no one updated the forecast for the new component to reflect the ramping volumes that were planned. Since the distributor and manufacturing service provider did not realize the oversight, no plans were made with the component manufacturer to ensure the needed quantities would be in place. The component distributor had a small number of the components in inventory and quickly delivered initial orders, giving the manufacturing service provider the feeling that the part was readily available. Finally when a large order

Figure 2. A typical virtual supply chain in the computer and electronics industry.

for the component was placed, the distributor realized the mistake, but it was too late. The component manufacturer could not deliver the component in time for the pending ramp up. For the OEM, this meant having to go to the channel partner and explain why the new product would have to be delayed for several weeks. The channel partner had already planned a major product rollout supported by advertising and had made many promises to its retail customers. After tense negotiations, the component manufacturer offered to switch production at one of its plants to expedite the chip, but at a cost of \$3 million. In the end, rather than delay the product introduction the three partners, the OEM, electronic manufacturing service (EMS) provider, and component distributor split the cost and expedited the chip.

While not all coordination mistakes are as costly as this one, the cumulative cost of many smaller mistakes is significant. Even managing simple tasks, such as the approval process for engineering changes, is a nightmare in many organizations. Proposed changes are often routed by phone, e-mails, text messages, and meetings to capture the necessary approvals to be released to manufacturing. Once released, changes often come as a surprise to manufacturing and sourcing partners, adding cost and time. On a routine basis, mistakes that create short delays in component deliveries to the EMS mean that reserved capacity at the EMS will go idle waiting for the part. In cases where the delay is clearly related to stumbles in the OEM product change process, the EMS may ask the OEM to help pay for the cost of the disruptions, typically \$5000–\$10,000 per day. Of course, these costs are small when compared to the substantial effect on total supply chain cost and potential revenue loss from delayed products.

To solve these problems, many firms—from Hewlett-Packard and General Motors—created their own homegrown design tools to help better coordinate designers and manufacturers. Many third-party companies, including CAD and workflow software vendors, also jumped into product data management market. Yet maintaining up-to-date product content is not enough.

The information must be shared with supply chain partners. A myriad of proprietary systems, while improving data quality, often hinders coordination between supply chain partners.

Today, a strong set of product collaboration software vendors such as Oracle and PTC offer web-based services that dramatically improve the ability of the supply chain members to communicate and collaborate with one another about new or changing product content. By bringing together all product content including drawings, BOM, approved vendors, process instructions, and a complete product history into a single portal, web-centric systems automate many painful tasks. For example, using such a system, a designer making an engineering change can work through a web browser to create the proposal. For each change, comments and product history is included so anyone examining the product can see why changes were made. When the proposal is complete, the software simply generates an e-mail containing a hyperlink to the proposed change to all of the people on the product team. By clicking on the hyperlink (with appropriate security), those who need to approve the proposal can see the changes, including drawings and product history. If the approvers agree with the change, they simply click an acceptance button and their response and comments are recorded with the proposal. After that, anyone who looks at the proposal could see who has accepted it thus far and who has not yet registered an acceptance or rejection. When all the required team members have approved the change, the system will automatically notify everyone related to the product that the change has been approved and release it to manufacturing and procurement.

As we have seen, synchronizing product data management translates into many cost savings. However, a far more interesting impact of a web-centric approach is how it changes the process of content management. Traditionally, distribution of product content follows a push process with the design engineers making product design decisions and sending those decisions to others in the supply chain. In disconnected push

systems, changes are expensive and thus are discouraged. Without instant access to content information, others within the supply chain operate with old information. More importantly, communication about product content is slow, hindering feedback from supply chain partners.

For example, if a designer specified a new component or product change that made the manufacturing process more difficult or affected the end quality of the product, it may take days or weeks for the supply chain partners to discover the issue and provide appropriate feedback. Automating the change process reduces the time and cost of engineering changes, making it possible to turn out frequent design improvements. Allowing supply chain partners to see the most recent information and suggest changes enables true collaboration and concurrent engineering where all supply chain partners participate in the design process. For example, a firm selling products worldwide could get feedback from regional partners, ensuring that the product would conform to local tastes and regulations well before the design is finalized. This leads to better products with fewer defects, improved functionality, and lower cost. The result is increased revenue.

ENSURING FRESH PRODUCTS—THE APPAREL INDUSTRY

The apparel supply chain is equally complex. Even simple garments like t-shirts are often touched by hands in several countries before ending up in the target markets of Europe or the United States. A more complex product, like a winter parka, often contains components from all over the world: snaps from Germany, zippers from Japan, insulation from China and Thailand, and the outer shell from Taiwan. To manage this complexity, many brand owners work with facilitating agents like Li & Fung who add value by coordinating the far-flung supply chains.

Brands and agents that bring their products to market orchestrate a long supply chain starting with fibers (wool, cotton,

synthetic) that are spun, woven, knit, and dyed in large mills, then on to cut-and-sew assembly operations, and finally laundry and finishing facilities before joining a global distribution system. With components like zippers and snaps added along the way, the final garment is the joint effort of many companies like DuPont (fiber), Burlington (mill), Kellwood (cut and sew), Liz Claiborne (brand), Dillard's (retailer), along with numerous transportation providers, freight forwarders, export agents, and warehouse providers. This whole process typically takes 6–12 months. The actual cycle time through the system is far less. Including transportation times, the value added cycle time without problems or changes is more like four to eight weeks. But along the way, the complexity of coordinating the product definition and managing the associated miscommunications across multiple companies slows the process to a crawl. So brands routinely begin working on their product lines well over a year before the selling season.

One of the biggest challenges in the industry is simply defining the product. Each garment has many technical specifications. First, there is the fiber and fabric itself. Working with fiber producers and mills, brand designers first must define many attributes of the fabric: its make-up, texture, weight, associated strength and elastic qualities, color, and finish. Even for what seems like a simple product, like jeanswear, this process can take months. After developing the concept with the brand, the mill runs a pilot production run of the fabric and submits it for testing. After review with the brand, changes are made and another pilot is run. Because of the scale of a high volume mill, each pilot run means producing several thousand yards of material that ultimately gets scrapped or dumped as off-goods. Getting the fabric right can mean multiple trials—each requiring weeks (Fig. 3).

But developing a technical specification for the fabric is only the beginning. Artwork for prints that are transferred to the fabric surface come next. Then there is the specification of the garment itself—the patterns, cutting and sewing instructions,

Figure 3. The fabric development process.

sizing specifications, and preferred vendors for buttons, snaps, zippers, and other components. Together with the BOM, associated drawings, process instructions, testing specifications, and technical color definitions, the total information content defining each product is massive. Even final garment finishing can be complex. For jeanswear products, the science behind laundering the garments to achieve the desired look is a key area of competition among brands and a high value-adding step to the garment.

As with many old industries, the information management supporting all the different facets of a garment specification has been slow to keep up with the increased complexity of the supply chain. Ensuring that everyone in the supply chain has an accurate and up-to-date description of the product is one of the biggest challenges. Like all products, once designed, garments are subject to many design changes in the preproduction phases. Typical products see more than 50 changes or enhancements before production is complete. And often changes made by brand designers are slow to reach the production floor of a contract manufacturer. In many companies, the change process is conducted through phone, e-mails, and test messages—all poor means of managing a distributed, complex supply chain. An executive at Burlington lamented that the change process looks like a child's whispering game. Starting at one end of the chain, a designer may call a manufacturing coordinator requesting a change to the left rear pocket of the pants. But, by the time the request makes its way to the manufacturing floor in Mexico, the request becomes a change to the right front pocket.

Getting the right information to the right people at the right time is the biggest challenge. Equally important is visibility to the entire product and sourcing team with a documented history of product changes. All too often, a change made by one member of the design team would be unseen by others creating confusion and finger pointing. Off-spec products arriving at a brand distribution center would be turned back by inspectors only to find out later that a single manager in the chain verbally approved the changes.

At Liz Claiborne, the first step toward information integration was bringing designers on-line using a consistent set of tools. Designers, long focused on hand sketching, were hesitant to move to computer-aided design. The organizational change of bringing hundreds of users on-line with digital design tools was painful, but after a five-year effort they have cut design time by 50%. Yet firms like Liz Claiborne found out that automating the design process, while improving internal efficiencies, did not help solve the supply chain problems. Vendors, who were less technically sophisticated or used different proprietary design systems, could not profit from the digital product designs. Often artwork created in a CAD system by a brand would be printed and shipped by overnight mail to a manufacturing partner where the document would be scanned (redigitized) to drive the manufacturing system that actually created the material. Even for those who could use the digital artwork, moving very large files over the web required more than simply attaching the CAD file to an e-mail message. It required a content management system that provided centralized

product information, where changes could be tracked and everyone was sure to have the most recent information.

At Dillard's, information transfer between in-house private-label designers and their 50 subcontracting partners once depended on massive faxing and overnight mail shipments. At a subcontractor's in India or China, the collection of documents would arrive over a period of days and weeks—completing the specification of the products. However, if there was a change in the design and assembly process, the product would be side-lined until the issues could be resolved and the required people in each organization had signed-off on the changes. When crunch time came, changes often happened over the phone or via e-mail with others in the design team left out of the loop, causing confusion and mistakes.

Tormented by the rising cost of complexity, many apparel designers began adopting digital design systems over 10 years ago, but like Liz, found that transferring the information within the rapidly disintegrating supply chain was tedious. Large firms like Gap and Limited invested in their own systems only to be paralyzed by the integration issues. With the opportunities of moving design processes onto the web, third-party apparel product management software companies like Lawson and Gerber Technology began developing web-based solutions. Levi's was one of the first large apparel companies to begin implementing a collaborative product management system from Lawson (then Freeborders) to facilitate fabric development, linking textile mills to Levi's product development, sourcing, pattern-making, and quality. For Dillard's, even the simplest features of these tools dramatically changed their product content management. Using a publishing and content management tool, Dillard's eliminated the faxing and e-mailing of product documents to their vendors. Each style is now managed with a virtual folder where designers and manufacturing partners can access documents over the web. With important product content stored in a single place, everyone is assured to be working from the most recent version. More importantly, changes cannot occur without being visible to

all parties. E-mail is limited to reminders to check changes in the folder and no changes can be made outside of the system. Besides saving weeks in communication time, the system helped eliminate costly mistakes and confusion.

Liz Claiborne implemented a similar system, cutting weeks out of the cycle time. At Liz, the time saved using a web-based system ensured more on-time deliveries and helped avoid costly markdowns due to late shipments. In some cases, with extra time in the design cycle, products could be further improved or shipments could leverage less-cost ocean transport rather than air freight. The advantages of even a simple web-based system are enormous and include the following:

- reduced cycle time;
- faster time to volume production;
- reduced scrap costs and mistakes;
- fewer markdowns due to late arrivals;
- secure environment with less paper and e-mailed documents;
- more reuse of standard design elements saving time in the design process;
- archived product history and change information leading to better accountability.

For contractors and mills, getting the product right the first time reduces scrap and costly delays that drive down manufacturing utilization. But escaping the supply chain tensions and the endless blame game may be one of the biggest benefits.

Collaborative systems can also be used by upstream suppliers, allowing vendors to share everything from product assembly specifications to more complex specifications of the fabric itself. For example, with its extensive experience with fibers, DuPont is able to work with textile mills to help them better use Lycra (a DuPont fiber) in manufacturing. As with many other industries, trust is important to successful collaboration. Decades of cost-focused procurement resulted in an environment of distrust that sometimes hinders firms from working together.

Figure 4. Maintenance review board (MRB) process.

COLLABORATION WITH CUSTOMERS—THE AEROSPACE INDUSTRY

In industries with long-life products, like construction equipment or aerospace, product collaboration has moved far beyond the initial product design to ongoing service innovation. Consider the case of BAE Systems Regional Aircraft, a UK-based company that provides postsales customer support for regional aircraft operators such as SWISS, Emerald Airlines, and Air Wisconsin. BAE Systems recently implemented collaborative software in its maintenance review board (MRB) process, the process by which BAE Systems and its customers (the operators), under the oversight of regulators, review and revise the maintenance review board report (MRBR) for each model of aircraft. The competitiveness of both BAE Systems and its customers has increased through this collaboration. And trust issues are being addressed along the way.

BAE Systems is responsible for customer support, engineering, and asset management activities covering a worldwide base of 160 customers operating over 1100 aircraft, in addition to managing a trading-and-leasing portfolio of some 350 aircraft.² BAE Systems currently supports the BAE Systems 146/Avro RJ, ATP, JS41, and JS 31/32 commercial aircraft models.

As part of its customer support activities, BAE Systems maintains the regulator-mandated MRBR for each model of plane. This manual is used by operators to create

their maintenance programs. While there has always been an opportunity to update maintenance procedures based on the experience of operators, relatively few changes have been made to these manuals. Updating has been limited by the labor-intensiveness and structure of the MRB process, as well as by the lack of collaboration with customers in this area. For example, as of 2004, while the BAe146/RJ model was 23 years old, the MRBR was on Revision 11. The fact that it was still a typewritten document also impeded updates.

The regulator-approved MRB process progresses as follows (Fig. 4): A proposed change (item) is introduced by an operator. The item is then discussed, analyzed, and voted on by the working group, a group including representatives from BAE Systems, major operators, and the regulating agencies (US Federal Aviation Administration (FAA), UK Civil Aviation Authority (CAA), and Transport Canada). Each operator in the working group gets one vote. If the item is approved by the majority of those casting votes, the revision to the MRBR is drafted and submitted to the Industry Steering Committee (ISC), a group including higher-level representatives from BAE Systems, the operators, and the regulators. If the manual revision is approved by the majority of ISC-member operators, then it is incorporated into the next revision of the MRBR. Finally, operators revise their maintenance programs to reflect the revised MRBR.

Traditionally, the intent was to issue a new revision of the MRBR once a year. BAE Systems accumulated and analyzed items submitted by the operators, and

²BAE Systems press release, January 2006.

then submitted them as approximately two 250-page packets for discussion at an annual three-day meeting of the Working Group. Based on that meeting, approved items were submitted as a group to the annual three-day meeting of the ISC. Thus, the number and depth of items that could be addressed was limited by the deliberation time per item and the meeting length. During the 1990s, an average of 20 changes per year were made to the BAe146/RJ, and an average of 10 items were carried over to the next meeting due to lack of time. (The 2006 MRBR for the BAe146/RJ included 1722 maintenance tasks).

Things started to change in mid-2004, when BAE Systems saw the opportunity to improve the competitiveness of its planes and reduce the operating costs of its customers by lengthening the maintenance intervals (time between scheduled maintenance) for its planes. This could only be done through close collaboration with the operators, as they had both the reliability data and the experience-knowledge that would be needed for making these changes without adversely impacting safety or availability of aircraft. Furthermore, it would be the operators that would cast the votes determining whether or not the changes would be adopted.

In mid-2004, BAE Systems established the maintenance optimization program (MOP), an 18-month effort to review "A" Check and "C" Check items for its BAe 146/Avro RJ and ATP models. The program involved analyzing all 1722 maintenance tasks for the BAe 146/RJ model and 555 maintenance tasks for the ATP model.

BAE Systems proposed to the operators and the regulating authorities that they implement a collaborative software tool called ForumPass developed by Exostar LLC. ForumPass is a secure on-demand solution for business collaboration built on top of Parametric Technology Corporation's Windchill collaboration engine ProjectLink. The collaborative software tool allows the working group to discuss proposed maintenance changes on-line as a stream of individual items, rather than in an annual face-to-face meeting as a large group of

items. After doing a pilot project, the group approved the implementation.

Implementation of the ForumPass software was accompanied by changes to the working group structure, work process, and organization. Rather than being structured around an annual face-to-face meeting of a year's accumulation of items, the structure of the discussion interaction is now an ongoing on-line threaded discussion of a small group of rotating items. Work is done at the operators' (and the BAE Systems representatives') home sites, rather than at the BAE Systems site. The size of the working group expanded, from 8 voting members to 13 voting members, and from 3 additional nonvoting members to 6 additional nonvoting members. (Travel time and cost was no longer a factor limiting participation.) Several of these new members are operators with fewer, more recently purchased BAE Systems aircraft, so have less experience with those aircraft. A quorum is set once 70% of the members have responded on-line, and an item is approved if more than 50% of those responding vote "Accept."

Under the MOP program, 13 operators and BAE Systems discussed the 1722 maintenance tasks for the BAe 146/Avro RJ models over a period of six months. Lengthening of the intervals was approved for 70% of the tasks—roughly 1200 tasks. The AMM was reprinted six months after the commencement of the program, using ForumPass.

The MOP program has benefited both the operators and BAE Systems. Maintenance intervals have been lengthened by 25% or more on the BAe 146/Avro RJ and ATP models. The operators have lowered the cost of ownership for their planes, as well as the cost of collaboration with BAE Systems. Operators of the BAe 146/RJ fleet saw a reduction in direct maintenance cost ranging from \$9–31 per flying hour, depending on the model.

For many years, BAE Systems and other aircraft makers have engaged in customer collaboration, relying on their customers to initiate, deliberate (with BAE Systems), and vote to approve proposed changes to maintenance procedures, procedures that in the long run will determine the safety and reliability record of the aircraft. BAE Systems has taken customer collaboration a

step further by implementing collaborative software for its working group process. BAE Systems has benefited by having more competitive planes, which has boosted demand. In addition, BAE Systems can incorporate the knowledge it has gained through the MOP into the maintenance programs for those planes. Finally, BAE Systems has increased customer loyalty toward its service and spare parts business.

CONCLUSION

The focus of this article has been collaboration in product and service design. As we have seen, collaboration can occur anywhere in the supply chain, both with suppliers or customers. Of course there are many objectives of such collaboration, such as cost reduction (as in the electronics case), speed to market (as in the apparel case), or service (as in the aerospace case). Alternatively, the goal of collaboration may be to facilitate manufacture [8]; ensure robust, product platform architectures [9]; reduce the environmental impact of the product by enhancing recyclability [10] or its ability to be remanufactured [11]. Recovery, remanufacturing, recycling, and carbon reduction pose many opportunities and challenges [12] for designers and supply chain managers—for a discussion of closed-loop supply chains [13] see the article titled *Take-Back Legislation and Its Impact on Closed-Loop Supply Chains*. Likewise, besides collaboration on the product/service design, there are many opportunities for firms to collaborate on the management of the supply chain—for a discussion see the article titled *Supply Chain Coordination*. Given both the range of objectives of collaboration and the number of possible participants, significant research opportunities exist in better harmonizing the collaboration goals (e.g., carbon versus cost, speed versus service) as well as enabling and motivating partners to participate.

PROGRESSIVE ADAPTIVE USER SELECTION ENVIRONMENT (PAUSE) AUCTION PROCEDURE

RICHARD STEINBERG
London School of Economics,
London, UK

COMBINATORIAL AUCTIONS

In an auction involving multiple items, a bidder might have a higher valuation for a specified set of items than the sum of his valuations for those items individually. In such a case, the bidder is said to have a *synergy* for those items and those items are said to be *complementary* for that bidder. A *combinatorial auction* is an auction in which bidders can place bids on combinations of items, called *packages*, rather than just on individual items. Without the allowance for package bidding, a bidder would be exposed to a possible loss if his bids included synergistic gains that might not be achieved; this is called the *exposure problem*.

The package bidding of combinatorial auctions eliminates the exposure problem for the bidders, but gives rise to the *winner determination problem (WDP)* for the auctioneer. This is the problem of determining the winning bids by labeling bids as either winning or losing so as to maximize the sum of accepted bids, under the constraint that each item can be allocated to at most one bidder. In practice, this is a computationally intractable problem for any auction of significant size, since the WDP is equivalent to the weighted set packing problem and thus is NP-hard [1].

One might try to achieve *computational tractability*—that is, solvability in polynomial time—for the WDP by restricting the package bids in some way. However, when combinatorial auctions were first considered for use in the US Federal Communications Commission (FCC) spectrum auctions, McAfee [2] and other economists

argued that the only choice was either completely disallowing, or permitting all possible, combinatorial bids. This principle thus asserts that a combinatorial auction should allow all possible combinatorial bids, that is, it should be *fully combinatorial*.

There is also a mathematical reason for not restricting package bids. Although perhaps not their intent, Rothkopf *et al.* [3] showed that essentially any restriction that would reduce the WDP to a computationally tractable problem will, of necessity, result in a setting that is too simplistic for most real-world auctions. For example, they examine cardinality-based structures, and consider the restriction of allowing package bids to include only up to k items, for some k . How small must k be in order that such combinatorial auction structures will be computationally tractable? Answer: $k = 2$. In other words, restricting package bids to contain only two items will indeed yield a WDP that can be solved in polynomial time, but allowing packages of up to three items will already result in a WDP that is NP-hard.

Another approach would be to allow the auctioneer to approximate the solution to the WDP. However, there is the doubtful matter of whether bidders would find an approximate solution to be acceptable. Even if an approximation were to be acceptable, there is the question of whether a good approximation to the WDP is even possible. Hastad [4] showed that, unless any problem in NP can be solved in probabilistic polynomial time, then for any $\varepsilon > 0$, there is no polynomial-time algorithm that guarantees an approximate solution to the WDP within a factor of $n^{1-\varepsilon}$ from optimal, where n is the number of submitted bids.

Two additional issues arise in combinatorial auctions. The first is the desideratum that a losing bidder has the ability to see why he lost; a property known as *transparency*. In single item auctions, transparency is not an issue, but in combinatorial auctions, where the set of winning bids is by no means obvious, transparency may be difficult to achieve.

The second additional issue is known as the *threshold problem*. Due to the fact that bidders on smaller packages may not have the resources individually to overtake a large package bid, or might not have the ability to coordinate with each other in order to do so, the allowance of package bidding can favor bidders seeking larger packages. It would be desirable to have a combinatorial auction procedure that alleviates this bias.

There is in fact an auction that addresses all these issues. The PAUSE (progressive adaptive user selection environment) procedure introduced by Kelly and Steinberg [5] is a combinatorial auction that is transparent and allows all possible package bids, that is, is full-combinatorial, and where the auctioneer does not face the WDP but instead need only solve a polynomial-time problem. Further, PAUSE mitigates the threshold problem. (See the section titled “Additional Properties of PAUSE.”) In addition, the allocation obtained by PAUSE is *envy-free*, that is, at the conclusion of the auction, no bidder will desire to exchange his allocation with that of another bidder. In order to explain how PAUSE works, we will first discuss in the next section an earlier, noncombinatorial, auction procedure.

THE SIMULTANEOUS ASCENDING AUCTION

The *simultaneous ascending auction* (SAA) [6] for auctioning multiple items proceeds by discrete rounds, where multiple items are auctioned simultaneously, each with its own price. Each bidder is free to bid in a round on any number of items, subject to: (i) a *minimum bid* increment; (ii) an *activity rule* that restricts the pace of the bidding; and (iii) an allowance for *bid withdrawal*, whereby players can withdraw their bids subject to a payment equal to the difference between the withdrawn bid and the bid that replaces it. The auction terminates when a round completes in which no new bids have been submitted on any item. The winner on each item is the high bidder on that item, who is required to pay his bid.

The minimum bid increment assures that the auction concludes in a reasonable amount of time.

The activity rule requires bidders to maintain a minimum level of bidding activity during the auction where, as the auction progresses, the level of activity increases. The activity rule forces a bidder desiring a large quantity of items to bid for a relatively large quantity earlier in the auction, thus preventing against the “snake in the grass” strategy, in which a bidder deliberately maintains a low level of activity early in the auction and then greatly expands his demand late in the auction. The activity rule also promotes *price discovery*, the process in which information about the bidding is revealed to the bidders, who have the opportunity to adjust their subsequent bids accordingly.

The bid withdrawal rule facilitates, to some extent, the realization of bidder synergies, but it can be gamed. In Australia, in 1993, two licenses for satellite-television services were offered by an auction that allowed for bid withdrawal. The licenses were won by two bidders by offering “startling high bids” [7]. However, it soon became clear that these two bidders had no intention of paying their winning bids, having put in a series of lower bids, and then proceeded to default on their highest bids, and then default on their next highest bids, and so forth until they finally purchased the licenses at considerably less than their original high bids.

PAUSE

The key idea of Kelly and Steinberg [5] is that the inherent computational complexity of combinatorial auctions cannot be eliminated, and thus the computational burden of evaluating a package bid is transferred to the bidder submitting the bid, leaving the auctioneer to no longer face the WDP. Although in theory a bidder might face a computationally intractable problem, in practice the bidder may often have a relatively easy problem. The Kelly–Steinberg design is called *PAUSE*.

PAUSE proceeds in stages comprised of discrete rounds. In stage 1, a SAA is held for all the items, thus facilitating price discovery. In stages 2, 3, . . . bidders can realize their synergies via package bidding. However, the bids on packages cannot be submitted in isolation: each bidder is required to submit them

as part of a *composite bid*, which is a set of nonoverlapping package bids (including individual bids) that cover *all the items in the auction*. Of course, a bidder will generally be interested in bidding only on a subset of the items in the auction—and in any given round, perhaps only a subset of these. A *composite bid consists of the bidder's own bids, together with previously submitted bids by any of the bidders*.

In general, there are only two restrictions on composite bids. First, for a composite bid placed in stage k , the package bids that comprise it are limited in size, viz., each package bid cannot contain more than k items each. Second, composite bids are restricted in how they use bids from other bidders, viz., when previously submitted bids from a bidder Y are included in the composite bid, the bids from Y must have all been submitted by Y in a single round of the auction.

The following example illustrates composite bidding (see Fig. 1). There are six items in the auction: $\alpha, \beta, \gamma, \alpha', \beta', \gamma'$ (Fig. 1a). Stage 1 ended with a bid of 5 on each item,

respectively, by bidders A, B, C, D, E, F, and consequently a revenue to the auctioneer from these six bids totaling 30 (Fig. 1b).

Stage 2 ended with a standing composite bid by bidder B consisting of the following component bids: 11 by bidder A on the package $\alpha\alpha'$, 20 by bidder B on package $\beta\beta'$, and 14 by bidder C on package $\gamma\gamma'$, with revenue to the auctioneer totaling 45 (Figure 1c).

At the beginning of stage 3, two composite bids are submitted from Bidders A and E. Bidder A's composite bid consists of a bid from himself of 35 on the package $\alpha\beta\gamma$, together with the earlier bids of 5 each on α', β' , and γ' , respectively, from bidders D, E, and F, with revenue to the auctioneer of 50 (Fig. 1d). Bidder E's composite bid (Fig. 1e) consists of a bid from himself of 30 on the package $\alpha\alpha'\beta'$, together with the earlier package bid of 14 on $\gamma\gamma'$ from bidder C, and the earlier bid of 5 on β from B, with revenue to the auctioneer of 49. Since both A and E have submitted valid composite bids, the auctioneer chooses bidder A's composite bid, as it yields higher revenue. The auction progresses from there,

α	β	γ
α'	β'	γ'

30 _E		14 _C

(e) Bidder E's stage 3 composite bid. Auctioneer revenue: 49.

Figure 1. Illustration of composite bidding.

with bidders submitting composite bids of increasingly higher revenue until the auction terminates.

Composite bidding has three important consequences: (i) the auctioneer is relieved of the combinatorial burden of the WDP (since he needs only choose the highest valid composite bid); (ii) each losing bidder can compare his bids with the winning composite bid to see why he lost; and (iii) at the conclusion of the auction, no bidder would prefer to exchange his allocation with that of another bidder. These first two features are, of course, computational tractability and transparency. The third feature is *envy-freeness*.

Note that a package bid can be described as a special type of “contingent” bid in the sense that the bidder is offering to serve all the properties in the package or none. PAUSE handles more general forms of contingency as well through the allowance of *Boolean bids*, that is, strings of package bids together with Boolean “AND,” “OR,” and bracket connectors (bracket being left bracket or right bracket), together with a value or values.

THE STANDARD PROCEDURE VERSUS THE PAUSE PROCEDURE

The example in Figs 2, 3, and 4 compares the workings of the PAUSE procedure with that of the “standard” combinatorial auction procedure in which bidders submit bids to the

auctioneer who then faces the WDP. Consider an auction on four items as shown in Fig. 2. (You may think of this diagram as representing four adjacent parcels of land being offered for sale in a real estate auction.) There are three bidders such as ●, ○, and ●, who have interests as shown. Thus, bidder ● does not value any one of the items individually, but has positive valuations for the two top and the two bottom items; bidder ○ has positive valuations for each of the items individually, but has no synergies for any set of items; and, bidder ● has a synergy for three of the four items, as well as having a positive valuation for one of those three items on its own.

Figure 3 shows how the “standard” procedure operates. Bidders submit all their package bids, including bids on individual items, leaving the auctioneer to solve the WDP, an NP-hard problem. This may go through a number of rounds until a stopping rule terminates the auction and reveals the allocation to bidders. This solution is not transparent, as the step in which the auctioneer solves the problem is a “black box.”

Figure 4 shows how the PAUSE procedure operates. In stage 1 of the auction, the bidders submit their individual bids only. Thus, bidder ● submits no bids, ○ submits all four of his bids, and ● submits his bid for the single item only. The auctioneer has a simple problem of determining the winning set of individual bids via a SAA. In later stages

Figure 2. Four items and three bidders.

of the auction, each bidder can submit a single composite bid in each round and, as in stage 1, this process may go through a number of rounds until a stopping rule terminates the process. As it happens, bidder ● submits a composite bid including the top two items as a package from him, and fills out the bottom two items with previous bids from bidders ○ and ●. Bidder ○ has no synergies for any items, so acts passively by refraining from

submitting any composite bid. Bidder ● submits a composite bid consisting of the 3-item package bid from him, together with a bid from bidder ○ on the remaining item. The auctioneer needs only compare the composite bids submitted bidders ● and ●; specifically, by checking the validity of these composite bids and choosing the one with the highest revenue, an easy task. The solution is of course the same as obtained under the

Figure 3. Standard procedure.

Figure 4. PAUSE procedure.

standard procedure, but here the procedure is transparent. Every bidder can see how the solution was obtained.

FORMAL DESCRIPTION OF PAUSE

Composite Bids

Let $\Omega = \{\alpha, \beta, \gamma, \dots\}$ denote the set of *items*, where $|\Omega| = m$, the number of items in the set Ω . Label packages $k \in \mathbf{K}(\Omega, A)$, where $\mathbf{K}(\Omega, A)$ is a set of subsets of Ω defined by a set of *attributes* A that are computationally tractable for the auctioneer to verify for each member of $\mathbf{K}(\Omega, A)$. Let

$$\mathbf{K}_q = \{k \in \mathbf{K}(\Omega, A) : 1 \leq |k| \leq q\},$$

where $|k|$ denotes the number of items in package k , that is, the *size* of package k . Thus $\mathbf{K}_q$ denotes the set of packages up to size q possessing attributes A . The set A would normally include the attribute, call it A_0 , that previously submitted bids from a bidder Y that are included in the composite bid must have all been submitted by Y in a single round. (Another attribute might be, for example, in the case where the items are parcels of land, that the items in each package bid must be geographically contiguous.) When we do not need to make the set A explicit, we can write $\mathbf{K}(\Omega, A)$ somewhat more concisely as $\mathbf{K}(\Omega)$.

A partition $\mathbf{P} = \{b_1, b_2, \dots, b_r\}$ is a collection of packages called *blocks* $b_1, b_2, \dots, b_r \in \mathbf{K}(\Omega)$ such that $\bigcup_{i=1}^r b_i = \Omega$, and $b_i \cap b_j = \emptyset$ for $i \neq j$. If a bidder X places a bid at price $p(b)$ on a block b of size k , then the triple $(X, b, p(b))$ is called a *block bid*.

A *composite bid* by bidder X is a collection of disjoint block bids that cover all the items of the auction. Note that a composite bid will, in general, contain block bids of other bidders in addition to one or more bids from bidder X . More formally, a composite bid comprises a partition

$$\mathbf{P} = \{b_1, b_2, \dots, b_r\},$$

together with an *evaluation*

$$(E(\mathbf{P}); p(b_1), p(b_2), \dots, p(b_r)),$$

where

$$E(\mathbf{P}) = \sum_{i=1}^r p(b_i).$$

Thus, a composite bid consists of $3r + 1$ pieces of information (in addition to the identification of the bidder placing the composite bid) capable of registration in a database. The first piece of information is the total value of the composite bid, $E(\mathbf{P})$. The remaining $3r$ pieces of information are, for i ($i = 1, 2, \dots, r$):

1. The specification of the block b_i
2. The bid $p(b_i)$ on the block b_i
3. The identity of the bidder for block b_i .

All $3r + 1$ pieces of information are available from the database to all bidders.

Specification of the Auction Mechanism

Stage 1: Bidding on Individual Items.

The Bidders. Each bidder submits bids on one or more items. In each round, there is an *improvement margin requirement*.

The new bid must improve on the previous best bid on that item by at least ε and less than 2ε , for a specified ε .

The Auctioneer. In each round, for each item the auctioneer confirms that a bid on that item is *valid* by verifying *increment validity*.

The bid satisfies the bounds of the improvement margin requirement.

In each round, the highest valid bid on each item is accepted by the auctioneer. The stage ends when bidding ends on all items. At the conclusion of stage 1, the auctioneer registers in a database the leading (i.e., high) bid on each item to their respective owners, as well as the stage in which their owner submitted the bid, and the stage and round in which the bid was submitted. This database is maintained by the auctioneer.

(Note: Stage 1 can be divided into sub-stages along the lines of the simultaneous ascending auction structure used by the US FCC, where progressively more severe activity rules are imposed over stages. See Ref. 8 for more details.)

Stages $k \geq 2$: Package Bidding.

The Bidders. Each bidder submits a single composite bid, $\mathbf{T}$ (which, by definition, covers all the items in the auction). In each round, there is an *improvement margin requirement*:

Let $w(\mathbf{T})$ denote the number of *new* bids in the composite bid. The new evaluation must improve on the previous best evaluation by *at least* $w(\mathbf{T})\varepsilon$ and *strictly less than* $2w(\mathbf{T})\varepsilon$. (Thus, the requirement is an average improvement per block of at least ε but less than 2ε .)

In stage k , each component b_i of a bidder's partition $\mathbf{P} = \{b_1, b_2, \dots, b_r\}$ is restricted to $b_i \in \mathbf{K}_k$, where $p(b_i)$ is either a new bid for block b_i , or a registered bid.

The Auctioneer. In each round, the auctioneer checks *composite bid validity* by checking:

1. *Bid Validity.* Each bid contained in the composite bid that is asserted to be registered in the data base is indeed so registered, and that new bids in the composite bid identify correctly the bidder for block b_i , and satisfy $b_i \in \mathbf{K}_k$.
2. *Evaluation Validity.* The value of the composite bid, $E(\mathbf{P})$, is indeed equal to $\sum_{i=1}^r p(b_i)$, the sum of the bids on each of its blocks.
3. *Increment Validity.* The value of the composite bid, $E(\mathbf{P})$, satisfies the bounds of the improvement margin requirement.

At the end of each round in stages $k \geq 2$, the new collection of valid bids on all the blocks from all the bidders is registered in the database to their respective owners, as well as the stage and round in which they submitted the bid. (Note that a composite bid might not be valid, but it may nevertheless, contain valid new component bids by the bidder submitting the composite bid. These valid new bids are to be registered in the database.) Further, the highest valid composite bid is accepted as the standing composite bid.

Thus, in each round, the auctioneer accepts *one* composite bid from among all the composite bids submitted by the bidders, but

updates the database with *all* valid bids on blocks from among *all* the bidders.

A stage ends when bidding ceases.

For suggested activity rules for PAUSE, see Ref. 5.

APPLICATION TO UNIVERSAL SERVICE SUPPORT AND MULTIPLE WINNERS

Kelly and Steinberg introduced the PAUSE mechanism for a specific application arising from the US *Telecommunications Act of 1996*, one of whose requirements was that regulators consider ways to reform the method of providing *universal service* subsidies for high cost areas. This refers to the situation that had been in place in the United States for many years, in which telephone companies were granted a monopoly to provide telephone service within their operating region, but had a concomitant responsibility to provide basic telephone service to all telephone subscribers within their region, no matter how costly. This was alleviated by a provision in which the telephone companies would receive subsidies for designated "high cost areas." Around the time of the passage of the Act, several parties advocated that "competitive bidding," that is, auctions, be used to determine universal service subsidies.

Kelly and Steinberg's paper was written in response to this suggestion. Since a firm might find it less costly to serve an area if it were to serve it together with other areas, a combinatorial auction was required. Kelly and Steinberg's universal service support auction was designed as a reverse auction using the PAUSE mechanism, where firms would bid for subsidies on specified areas and the winning firm would be the one that bid the lowest subsidy. Their design also allowed for competition within areas, that is, "multiple winners," a strong interest of the FCC at the time. The FCC's idea was that it could be useful to allow competition *in the market*, as well as competition *for the market*.

With the allowance for multiple winners, the auction design would need to minimize a form of collusion known as *price-level signaling*. This is the situation in which two or more players become aware that they are

actively interested in the same property on which they have the potential to share as multiple winners. Consequently, each firm bids noncompetitively so as to maximize its subsidy as a joint winner on the property. A discussion of how PAUSE minimizes price-level signaling appears in the section titled “Additional Properties of PAUSE.”

In order to accommodate multiple winners, the modifications to the basic PAUSE procedure are as follows. For the remainder of this section the reverse auction formulation will be employed, and the term for the areas will be “properties” rather than items. At the conclusion of stage 1, the auctioneer announces the number of multiple winners that will be accepted and necessary for each item χ , as determined by the auction’s *outcome rule*. One possible outcome rule (due to Milgrom [9]) has the following three-part formulation, where M_1 and M_2 ($0 < M_1 < M_2 < 100$) are specified in advance: (i) If at least one competing bid on χ is within M_1 percent of the lowest bid, then all firms that bid within M_1 percent of the lowest bid are designated as winners; (ii) if no competing bid on χ is within M_1 percent but one is within M_2 percent, then the two lowest bidders are winners; and (iii) if no bid on χ is within M_2 percent, then there is a single winner, viz., the lowest bidder. Denote the number of winners determined for property χ by $m(\chi)$. Before the start of stage 2, each item χ is replaced by $m(\chi)$ copies, $\chi_1, \chi_2, \chi_3, \dots, \chi_{m(\chi)}$, where each is allocated a nominal number of subscribers equal to $sub(\chi)/m(\chi)$, where $sub(\chi)$ denotes the number of subscribers in property χ .

The bidding rules from stage 2 onward are modified as follows. In order for a composite bid to be valid, there is the additional requirement that for each “multiple property” χ , the bid must not allocate χ_i and χ_j to the same bidder, for $i \neq j$. As before, the validity of a composite bid can be checked by the player constructing the composite bid, and this is to be checked by the auctioneer upon receiving the composite bid.

At the conclusion of the bidding, the $m(\chi)$ winning firms on property χ are each designated a $1/m(\chi)$ share of the responsibility on property χ . Specifically, the contractual

obligation carried by each winning firm is as follows:

1. The firm will receive its bid subsidy per subscriber on up to $1/m(\chi)$ of the total number of subscribers in that property;
2. The regulatory authority may require any firm with responsibility in that property who is not serving the full amount of its contractual share of subscribers to serve any unsubscribed subscriber in that property.

The particular subscribers that constitute a contractual share are not specified; the winning firm will compete with the other winning firms on that property for subscribers. Thus, there is an incentive for winners to actively seek to serve their share of subscribers, lest they be required to serve subscribers not of their choice.

A winning firm’s bid on property χ will in general be part of a composite bid. Thus, the limitation on the fraction of customers for which a firm will be subsidized prevents the firm from cross-subsidizing property χ from the other properties that comprise its bid. Each firm is free to compete for any or all the customer in property χ , although the firm will not receive subsidy for any subscribers beyond the share he has won responsibility for in the auction.

Kelly and Steinberg [5] point out that the method by which the numbers of multiple winners are determined is consistent with Milgrom [10] who showed that when there are no synergies, an optimal auction design entails endogenous market structure. In an appendix to their paper, Kelly and Steinberg describe a modification to PAUSE where the first stage is conducted as a sealed-bid auction.

More on the application to universal service can be found in Kelly and Steinberg [5], which had been submitted 3 years earlier *ex parte* to the FCC [11], the FCC’s related “Further Notice of Proposed Rule Making” [12, N.B. pp. 47–48 and 73–75], as well as Kelly and Steinberg’s comments in response to this document [13].

ADDITIONAL PROPERTIES OF PAUSE

Prevention Against Jump Bidding and Mitigation of the Threshold Problem

McAfee and McMillan [8] report a potential problem with SAAs, called *jump bidding*. This is where a bidder places a bid that significantly exceeds the required minimum required increment in order to signal an aggressive strategy to the other bidders not to compete with the jump bidder on the same item. This message discourages competition because it suggests that the jump bidder values the item more than anyone else. In Kelly and Steinberg [5], this is referred to more specifically as *price-jump bidding*. This is to distinguish it from another tactic they call *block-jump bidding*, in which a bid by a powerful bidder for a block of several items could be effective at preventing small bidders from piecing together a comparable composite bid.

In PAUSE, the improvement margin requirement reduces the possibility of price-jump bidding. The progression of allowable block size $k = 2, 3, \dots$, prevents block-jump bidding and mitigates the threshold problem. (Cramton [6] provides an example of how the absence of the upper bound on the improvement margin requirement can favor bidders seeking large aggregations.)

Minimization of Bidder Collusion

Klemperer [14] points out that a major concern for practical auction design involves the risk that participants may explicitly or tacitly collude to avoid bidding up prices. He specifically singles out the SAA where, early in the auction when prices are still low, bidders might be able to signal to each other who should win which items, and then tacitly agree to stop pushing up prices. Klemperer provides convincing evidence that this is what occurred in 1999 when Germany held a SAA for 10 blocks of spectrum. The auction closed after only two rounds, with Mannesmann and T-Mobile each ending up with half of the blocks at the same low price.

Under PAUSE, this problem of bidder collusion is less likely to occur, since the auction does not end at stage 1. In later stages of the auction, it is possible that another bidder

would place a package bid covering some of the items provisionally won by one (or more) of the colluding bidders. This could force one or more of the colluding bidders to raise their bids in order to stay in the auction.

In the version of PAUSE designed for universal service subsidy, which allows for multiple winners, a related type of bidder collusion is possible, called *price-level signaling* (see the section titled “Application to Universal Service Support and Multiple Winners”). However, in PAUSE price-level signaling is minimized by having the number of multiple winners determined prior to the combinatorial bidding stages that follow stage 1. Thus, most of the bidder surplus for the individual properties will have already been extracted. Any additional surplus mostly likely would be due to synergies, for which price-level signaling is very difficult to take advantage of, due to the fact that combinatorial bids overlap in ways that usually cannot be easily disaggregated.

FURTHER READING

Land *et al.* [15] focus on bidding behavior in PAUSE by considering in detail a general case of a two-item combinatorial auction. Mendoza and Vidal [16] develop two bidding algorithms for use in a PAUSE auction and analyze them via numerical methods.

Acknowledgments

The diagrams comparing PAUSE with the standard combinatorial auction procedure were devised together with Richard Gibbens. The author would like to thank Richard Gibbens, Frank Kelly, and Thomas Kittsteiner for helpful comments on earlier drafts of this article.

PROJECT-BASED ORMS EDUCATION

SUSAN E. MARTONOSI
Harvey Mudd College,
Claremont, California

There is much more to operations research and management science (ORMS) than rote application of formulas and algorithms. To effectively apply ORMS tools in the private and public sectors, students must also learn how to define an ill-posed problem; identify opportunities for cross-disciplinary methodology; choose an appropriate model; obtain, clean and analyze data; and decide when a model is useful. In addition, they must also develop the so-called “soft skills” such as professional and effective communication with stakeholders throughout the modeling and implementation process, project management, and effective team dynamics [1,2].

Ben-Zvi and Carton [3] and the references therein indicate that a traditional lecture-based course is insufficient for preparing students for managing ambiguities and decision making under uncertainty. Business and engineering school curricula focus on skill-development rather than the integration of multiple skills to solve a problem [3,4]. Grossman [5] and Reisman [6] encourage problem-centered, rather than method-centered, teaching with opportunities for hands-on work.

Projects, of all sorts and scopes, have been used in undergraduate and graduate ORMS curricula for decades to bridge the gap between the classroom, where tidy problems and clean data prevail, and the real world, where problems are complex and poorly defined, and data range from nonexistent to abundant but messy. In addition, project-based learning is prominent in other disciplines. The Accreditation Board for Engineering and Technology (ABET) requires accredited engineering programs to culminate in a major design project [7]. The Harvey Mudd College Clinic program, in which a team of undergraduates in their

final year completes a project posed by an external sponsor, spans their engineering, physics, computer science, and mathematics departments [8].

In this article, the author focuses on projects used in ORMS education. Common types of project-based educational activities that are described in the ORMS literature is outlined first: management games, case studies, class projects without external clients, curricular internships, and the so-called “field” projects with external clients. The author then focuses specifically on field projects with external clients and summarizes some of the best practices for instituting and maintaining such programs.

TYPES OF PROJECT-BASED EDUCATION

Management Games

In management games, teams of students are faced with fictitious but realistic business scenarios (and accompanying data) and must make a decision in real time. Often, management games are played repeatedly over a term, offering teams the opportunity to develop and refine their strategy, thus offering a project-like experience. The benefits of such games include

- learning the interrelation of functional specialties and applying cross-disciplinary knowledge;
- practicing decision making in a more dynamic environment than that afforded by a conventional case study;
- practicing decision making under uncertainty;
- low stakes environment;
- immediate feedback, typically via simulated financial outcomes, of the results of the team's decisions;
- illustrating organizational problems of team decision making;

- exploring game theoretic dynamics when multiple teams are acting as competing businesses within a same game; and
- improving one's decisions via repeated games, for instance, over the course of a semester [3,9,10].

Cohen and Rhenman [9] give an overview of the early use of simulation games in executive education. The first widely known business game was developed in 1956, based on military war games: American Management Association Top Management Business Decision Simulation. This game gave business executives the opportunity to gain experience in real-time decision making in a structured, fictitious environment. Players input their business decisions in the form of parameters, and the simulation output the results of those decisions in the form of business performance metrics. This game led to other business decision simulation games that were used in undergraduate, Masters, and PhD programs around the world.

More recently, Ben-Zvi and Carton [3] describe a business game course wherein students get practice in real-time decision making over the course of a semester through the use of the International Operations Simulation Mark/2000 game. Teams of students represent several companies that are operating in a simulated market environment. Each episode, the team makes a set of production and other operational and management decisions. All teams input their decisions into a database. The simulation runs, and the output is a set of financial reports for the companies. In addition to students observing the direct results of their decisions, they also begin to understand market dynamics as they witness the impact of their classmates' decisions on their company.

One downside of management games is the capital cost of any software [9]. However, free games are available on the internet, including the well-known MIT Beer Game [11]. This game consists of a retailer, a wholesaler, a distributor, and a factory who supply each other in a chain. In each round of the game, each party must place an order in the hopes of meeting its customers' demand. The

purpose of the game is to illustrate the value of information sharing across levels of a supply chain. Like other management games, it is dynamic and students work in groups to discuss their decisions [10].

Other recent examples include Refs 12–17, which are included in the Special Issue on the Use of Classroom Games in Management Science and Operations Research in *INFORMS Transactions on Education*.

Case Studies

A case study is a written scenario about a business situation in which a protagonist, typically a business executive, is faced with a managerial decision. Some cases are fictional, often anonymized versions of a true business situation, while many concern actual companies at critical points in their history. Cases are often authored by business school faculty who served as consultants to the company in question, advised a student consulting project, or maintain connections with their alumni in industry [18]. Cases are typically used in Masters of Business Administration (MBA) programs, and several business schools (e.g., Harvard Business School, the Ivey School of Business at the University of Western Ontario, and the University of Virginia Darden School of Business) are known for teaching almost exclusively using case studies.

Case studies bridge the gap between mastery of tools and techniques and their effective application to real-world problems [18]. Rarely do business problems conveniently pigeon-hole themselves within specific disciplines. Cases provide students with opportunities to apply interdisciplinary knowledge from across their education. Moreover, they demonstrate the role that quantitative methods can play within management [18]. In addition, there is rarely one correct decision to be made by the protagonist in the case, which allows students to use their creativity to consider many different options and interpretations. A good case has several possible directions and provides extensive information and data about the organization [19].

There are several models for using cases in the classroom. The simplest is an in-class

discussion of the issues of the case, either closely directed by the instructor to guide the students toward key points, or using “discussion leadership,” where students are completely responsible for directing the discussion toward key points [19]. In another model, students complete the quantitative analysis before the class and a student is selected to present the case to the class. In still another model, students can read and critique a completed case analysis [18,20]. In these examples, only one or two class sessions are spent discussing a single case. Some programs will look at a new case every class session [18], while others will intersperse cases among lectures and other classroom activities [21]. Although case studies are typically used in smaller classes, where the grading burden is less onerous and classroom discussion is more easily managed, Simpson [22] describes using cases in large classes with computer-aided evaluation of submitted assignments.

In a model that is closer to the “projects” theme of this article, students use a case study as the basis for a semester-long team project. In Ref. 23, the author describes a course at the Swinburne University in Australia in which students worked in teams of four to five students over 12 weeks to solve a case study. Each team appointed a project leader. At the end of the semester, teams gave oral presentations of their results.

In addition to providing the opportunity to synthesize multidisciplinary knowledge to make a business decision, cases also help students to develop soft skills such as communication (through in-class discussions and oral presentations), team work (in preparing the case solutions), and organization (in filtering through the provided data in the case to determine which pieces are the most critical) [20].

As stated in Ref. 20, cases can grow stale to instructors teaching the same course every year. The solution he discovered was to use articles from the journal *Interfaces* as a source of cases that student teams would try to improve on by developing their own models and solution approaches. In addition, there are several sources for published cases. Cases and accompanying

teaching materials are published in the journal *INFORMS (Institute for Operations Research and Management Science) Transactions on Education*. INFORMS also hosts an annual case competition, where authors of case studies can compete; participants are then encouraged to submit their cases to *INFORMS Transactions on Education*. Several business schools publish and sell cases authored by their faculty [24–27]. There also exist compilations of cases in book form, e.g. Refs 28,29.

Class Projects without External Clients

In addition to management games and case studies, a variety of projects can be incorporated into a course on ORMS to allow students to put theory to practice. The section titled “Student Field Projects” describes projects with external clients. In this section, projects that do not involve external clients are summarized.

These projects are typically one component (weighted less than one-third of the course grade) of a traditional undergraduate or graduate course. Some instructors use a collection of short projects, such as those described in Ref. 30. In these short projects, students observe and manage queues; follow news about service operations; analyze publicly available data, such as airline flight delay data; or map a service process and improve it, for example. Weal [23] describes a project in which groups of four or five students solve a real-world problem chosen by a member of academic staff.

In other courses, students are responsible for selecting their project topic, which can allow for great creativity. Belton *et al.* [31] describe a two-semester capstone course at the University of Strathclyde in the United Kingdom in which ORMS students in their final year design, as a class, a sequence of projects that they will complete. These projects range in structure from research papers, to game shows, to planning a start-up company. Anthony [32] and Martonosi [33] describe introductory courses at liberal arts colleges. Southwestern University and

Harvey Mudd College in which students identify their own projects of applying operations research (OR) methodology to a real-world problem. Projects have included course scheduling, locating electric vehicle charging stations, food pantry operations, and staffing of sports teams.

There are ample ways to incorporate the soft skills of OR into such projects. For example, Refs 32 and 33 report assigning intermediate deliverables such as a project proposal, a final report draft, and an executive summary, in addition to the final report; these deliverables undergo peer review by other students in the course to permit learning from each other. Students also evaluate each other's contributions both on the project teams and in the peer review groups to foster good teamwork. In Ref. 33, the quality of the written report counts for nearly half of the report grade, which encourages students to thoroughly proofread and edit their reports for clarity.

Grossman [5] explains that these course projects serve as a useful diagnostic tool for the instructor to recognize topics that have confused the majority of students. For instance, emphasis of models over modeling can result in students who do not know how to frame new problems. Instructors can use this feedback immediately to improve how they teach the material.

Curricular Internships

Some schools require students to complete internships in order to graduate to ensure that their graduates have had the opportunity to apply ORMS tools to practical problems. In an internship, the students work full time at an organization and have the opportunity to see firsthand how the methodology they have been learning in the classroom can be applied in a business setting. By working at the organization's site rather than completing a sponsored project on their own campus, they have greater access to the advice of professionals with domain expertise. The immersion experience also gives ample opportunity to develop professional communication, effective teamwork, and project management skills.

Although it is common for students to pursue internships during the vacation months of the academic year, this section addresses specifically the internships that are a required part of a university's degree curriculum. The extent to which these internships are arranged by the school for the students and monitored by faculty varies considerably in the literature.

In the shortest duration examples found by the author, students of the Cornell University's Semester in Manufacturing course spent three days participating in kaizen (rapid process improvement) activities at a company [34]. Bennet and MacFarlane [35] describe a program at the University of Strathclyde in the United Kingdom in which students spent three weeks working in a company's OR group as part of their graduation requirements.

Other universities require a full year internship for graduation. Weal [23] describes an OR program at the Swinburne Institute of Technology in Australia in which students were placed in jobs by a program coordinator who is also responsible for identifying participating companies. Moreover, representatives from the department visited the students three to four times during the year to monitor their progress and offer guidance. At the end, the students were required to write a report and deliver a poster session summarizing their experiences.

At the Eindhoven University of Technology in the Netherlands, a highly coordinated program was instituted involving six supply chains of three companies each. Students were assigned to work full time for one year at these companies. During that time, students implemented supply chain methodology from their courses to streamline interactions across each supply chain. The endeavor involved senior executives from each company and seven faculty advisors. The companies paid a large fee to the university to cover the cost of student stipends, faculty time, and travel [36].

Student Field Projects

In student field projects (also known as student consultancies), clients such as businesses, municipal offices, and nonprofit

organizations propose operational and managerial problems to teams of students. In contrast to an internship, field projects operate like a traditional consultancy: the student teams spend a period of time (typically one or two semesters) on the university campus solving the problem and present the final results to the client in the form of written and oral reports. Eaves [20] reports that the advantage of field projects over the examination of case studies is that field projects allow students to have a dialogue with the subject company that guides the project.

At many universities, field projects are used as the basis for “capstone” experiences, the culmination of a degree program. A capstone project permits students to synthesize material learned in earlier courses of their degree program, including courses fulfilling breadth requirements in other disciplines. At the undergraduate level, these include capstone programs in OR [37], operations management (OM) [38], and mathematics [39,40]. In other cases, the student field projects are conducted as one part of a more traditional course [41].

A wide range of project topics is reported in the literature, and the provided references can offer more detail on project scope. Abstracts of over 40 years of mathematics projects from the Harvey Mudd College Clinic Program, many related to ORMS, are found on the program’s web site [42]. Gorman [38] mentions projects involving machine scheduling, inventory management, process improvement, human resource planning and management, and statistical forecasting. Cooke and Williams [43] describe two software development projects. Armacost and Lowe [37] also list a wide array of topics including facility location; vehicle routing; production simulations; forecasting models for natural resource usage, catastrophic events and pension funds; and computer programming for database applications. They also summarize three successful projects. The first involved lawn maintenance crew routing at the Colorado Spring Cemeteries. Students used both a set-covering integer program and traveling salesperson heuristics to solve the problem as a multiple vehicle

routing problem, developed a prioritization scheme so that high priority regions of the cemetery lawn could be mowed once per week and lower priority regions less frequently, and identified resources necessary to achieve the cemetery’s original goal of mowing the full grounds every week. The second project pertained to pension portfolio management in which students solved quadratic programs to identify the efficient frontier of portfolio management strategies. They also developed a user interface sitting atop a simulation engine so that clients can select different strategies and assess their performance. In the third project, students created a custom database application to help the Colorado Air National Guard assess pilots’ accuracy on bombing runs. Although the authors report that this third project did not involve traditional OR methodology, the process of communicating with the client, clarifying the project’s objectives, and developing the tool to the client’s satisfaction gave the students valuable experience in the OR problem-solving process.

The educational benefits of student field projects include

- learning to frame ill-defined problems [37,43];
- learning to design the model with the end user in mind [5];
- improved communication skills [37,40,43];
- making connections between many disciplines within the field, or learning new tools to complete the projects [38,40];
- improved performance on course exams or in subsequent courses [5,44];
- developing project management skills [40];
- developing effective teamwork and leadership skills [40];
- understanding the ethical implications of professional work [39,40]; and
- learning basic research skills [40].

References in Ref. 43 point out that field projects emphasize frontline decision making over mere discussions of management in the hypothetical context of case studies.

Alumni also later report benefits from field project opportunities, such as improved job prospects, advancement within their organization, and the satisfaction of seeing their work implemented [38,45,46].

Student field projects have been formally assessed in several institutions. Gorman [47] reports on extensive assessment of the field project course at the University of Dayton, which included surveys of alumni zero to seven years postgraduation. Approximately 90% of respondents reported that the field project course was more valuable than other courses they had taken. In another study, 92% of students reported that the field project was an effective learning experience, and students who had completed a field project showed a statistically significant improvement in examination scores over students who had not [44]. At the University of Technology in Sydney, Quantitative Management Science students were asked to compare their capstone field project to other mathematics courses. Significant differences favoring field projects were found on the questions, “The subject was relevant to me,” “The subject was delivered in a way which was consistent with its stated objectives,” “My learning experiences were interesting and thought provoking,” and “Overall I am satisfied with the quality of this subject” [40].

In addition, institutional benefits in the form of revenue, research collaborations, publications, case studies, and community service are often reported in the literature [5,30,37,38,43,45,46]. Armacost and Lowe [37] summarizes two short teaching cases that resulted from student field projects at the US Air Force Academy. Grossman [5] provides references to several research papers and case studies that resulted from field projects.

Global Field Projects. While most student field projects work with companies that are local to the university, programs are emerging where students work with an international client, often in partnership with a team of students from an international university.

Kopczak and Fransoo [48] describe a “Global Project Coordination Course” between the Stanford University in the

United States and the Eindhoven University in the Netherlands. Three Stanford students partner with three Eindhoven students to work on a project having a corporate sponsor. For Eindhoven students, the course is a graduation requirement, whereas for Stanford students, it is an elective, and students submit résumés and cover letters in order to be selected. Through conference calls and periodic site visits to each other’s campuses and to the client’s site, the two teams of students work together over the course of one semester to solve the client’s real-world problem. In addition to offering the usual advantages of student field projects, these global field projects also teach the students important skills for effective cross-cultural collaboration. Stanford has partnered with several international universities and has run as many as 14 projects per year.

In a similar fashion, the Harvey Mudd College *Global Clinic* is a component of its college-wide Clinic capstone program. While the departmental Clinics have teams of three to five Harvey Mudd students working locally on a project sponsored by a client, in Global Clinic, a team of three Harvey Mudd students partners with a team of three students at an overseas university to work on a project sponsored by a multinational corporation or overseas nonprofit [49]. Harvey Mudd College has partnered with universities in Cambodia, Iceland, India, Japan, Puerto Rico, and Singapore; it runs one to three global field projects per year.

An important characteristic for the success of global field projects is that student abilities at the two partnering universities should be equally matched [48].

BEST PRACTICES IN STUDENT FIELD PROJECTS

Having established the many educational and institutional benefits of student field projects, it is now appropriate to consider the many details surrounding the implementation of such projects:

- Recruitment of projects;
- Fee structure;

- Confidentiality;
- Faculty role;
- Duration of projects;
- Team structure;
- Interactions between teams and clients;
- Deliverables;
- Grading;
- Institutionalizing these experiences;
- Challenges;

The literature presents many approaches to these details that have worked well in a wide variety of educational settings. This section attempts to summarize the approaches. In addition, Gorman [38] has a table describing the structure of several student field project courses.

Recruitment of Projects

Identifying good clients is repeatedly noted as critical to the success of a field project [38,39,48,50]. In addition to providing a project that is sufficiently challenging and interesting to the students, a good client is one who is invested in the outcome of a project and willing to communicate regularly with a team of students. Students can sense when the client has thrown together a problem statement that is of little importance, and they can lose motivation when this is the case [38]. In addition, the client must be willing to meet with students periodically, either face-to-face or via teleconference to ensure that the students are pursuing a direction that will be useful to the organization. Another desirable trait for some schools is the opportunity for future research collaborations and publications that could result from the project [46,48].

To find good clients, most field project programs rely heavily on their alumni base, local community organizations and businesses, industry affiliates of the university, personal and faculty contacts, companies that recruit through the school's career services office, and repeat customers because of the good reputation of their program [5,20,23,37–39,41,46,50]. Some programs, such as the Harvey Mudd College Clinic, recruit clients from across the nation and

rely heavily on teleconferences, e-mail, and one or two site visits for communication between the client and the student team [39]. The undergraduate capstone project at the University of Dayton uses an interview process to select clients, ultimately choosing ~60% of those organizations that have expressed an interest in participating. They prefer to maintain a mix of repeat clients and new clients, as well as a mix of industries and organization types [38].

Hand-in-hand with finding clients comes the problem of defining and scoping the project appropriately, which Bradley and Willett [34], Giaque and Sawaya [51], and others feel is the most critical determinant of project success. The first concern is ensuring that the techniques required to solve the problem are of the right level of sophistication for the students: too easy and the educational objectives of synthesizing material from several courses will not be met; too hard and the students might be unable to make progress. Armacost and Lowe [37] report needing to reject projects that are either too narrow (e.g. data gathering) or too broad. An additional concern is making sure the project scope will fit into the appropriate timeline [38,50]. Heriot *et al.* [52] recommend projects that have a tactical, rather than strategic, focus to reduce project scope. They also point out if the project scope is not defined in a way that is satisfactory to the client, then the client is more likely to back out. Borrelli [39] describes an iterative process in which the client presents several project ideas and works with the director of the field project program to select one idea and refine it suitably. However, despite one's best efforts, the project scope often changes as students start to understand the project better [38]. Importantly, the appropriate scope is highly dependent on the institution and its students; a project that can be completed in a semester at one institution might require a year or longer at another.

For field projects for large classes or that are requirements for graduation, the faculty member or program director in charge of recruiting clients has a duty to recruit a sufficient number of projects, which can be time demanding and stressful [52]. Eaves

[20] describes a personal rule of making five solicitations per day to prospective clients. Therefore, some field project programs require students to identify their own clients [5,30,43–45,52,53]. Business students, particularly part-time students, can often easily identify projects solving operational issues within their own employers; for these students, it is important that the selected project be of some benefit to them professionally. For undergraduates or full-time students, sourcing projects entails leveraging existing networks of contacts, cold-calling plant managers, and developing other useful entrepreneurial skills [45]. Once a client has been identified, students must also define the project in collaboration with their chosen client [45].

Student field projects offer several advantages to the client company:

- They are typically substantially cheaper than the cost of hiring a professional consultant (see the section titled “Fee Structure” and Refs 50 and 51), while providing access to talented students and *the faculty*.
- They are a good opportunity for a company to make progress on project ideas that have been sitting on a back burner without adequate staffing to pursue [20,43].
- They facilitate the client’s recruiting of students for jobs [5,20,39,41,50,51].
- Many programs have documented substantial savings for their clients: the University of Alabama Productivity Center estimates their 25-year contribution to be ~\$600 million in benefit to its clients [46]; the University of Dayton reports \$4 million in savings over eight years [38].
- They establish connections with academia [20].

Fee Structure

The ease of recruiting clients is somewhat dependent on the fee structure of the program. Many student field projects are free

to the client [37,38,45], and it is no surprise that these are the same programs that reported needing to turn away prospective clients. Gorman [38], Fraiman [41], Miller [46] report that these industry collaborations benefit both parties, and Armacost and Lowe [37] report that publishing papers and case studies based on the projects is an additional benefit. Haines [54] states that although the initial plan of the University of Toronto’s entrepreneurship program was to charge no fee to the clients (the program being funded by the Ontario government), the students in charge of managing the consultancy noticed that clients were less likely to be committed to a project for which they had paid nothing, suggesting that a nominal fee might be beneficial.

In some programs, clients pay direct expenses, such as software and travel [37,50,51]. In others, clients pay a fixed fee [39,48]. At Harvey Mudd College, the fixed fee goes to project expenses, administrative support, and institutional overhead [39]. Some programs are even more ambitious, securing state and federal funds in addition to client fees to support graduate students in addition to the items listed earlier [46]. Cooke and Williams [43] describe for-fee student field projects as an opportunity for businesses to outsource work at a low cost and for universities to supplement their income. They describe two programs, one at the University of North Texas where the clients pay a fee to the university, and a consultancy program at Clemson University where students are paid directly for their work, and a director bids on projects based on his or her contacts.

Confidentiality

Because any real-world project requires data, potential clients might be hesitant to participate in a student field project without requiring a confidentiality agreement. It is not uncommon for students, and occasionally faculty advisors, to sign such agreements [30,39]. In addition, care needs to be made in any public presentations that information is not being shared that could, for instance, preclude the client from filing a patent. This can usually be achieved by requesting the client

to vet any presentation materials in advance. The programs described in Refs 30 and 45 chose to have students conduct individual projects with their own employers in order to avoid the need for a confidentiality agreement. In Eindhoven's yearlong supply chain project described earlier, some company data was shared between companies within a single supply chain but never across different supply chains; clients restricted even some of the information communicated within the supply chain [36].

Faculty Role

There is wide variety documented in the available literature in the role of faculty members on student field projects, in terms of both technical contribution and time commitment.

Far to one end are student consultancies that are entirely student-run, such as that described in Ref. 54. Each term, the students filed as a legal partnership and eventually became an official nonprofit organization. Students identified clients and completed the work, occasionally, *hiring* faculty to act as consultants. Likewise, when students are responsible for selecting their own projects, the faculty advisor typically plays a backseat role [52]. On the other end of the spectrum, the faculty advisor or clinical professor acts as the project manager, and the students (undergraduates or graduates) are research assistants [43,46].

Most programs in the available literature describe a faculty role that is between these two extremes. The faculty advisor is primarily a coach who meets regularly with the team to monitor their progress and point them in the right direction but tries to allow them to proceed as autonomously as possible [5,20,23,37–39,48,53]. The faculty advisor is also responsible for quality control, by attending meetings with the client, reviewing reports, and helping the teams prepare for oral presentations [38,39,45,50,51]. Other important responsibilities include managing client expectations throughout the project [45], teaching supplemental topics that students need for the project [38,45], and tying up loose ends after project completion [51].

In addition, the number of teams a faculty member must advise can often dictate the amount of time that can be devoted to each team. The US Air Force Academy assigns a faculty instructor to the capstone course; this person must recruit 8–10 projects and oversee the program as part of that teaching responsibility. Faculty mentors then work more closely with a single team but do not receive teaching credit for doing so; they are compensated by the prospect of publishing the results of the project [37]. At the University of Dayton, the capstone course is taught by one or two faculty, each of whom manages roughly four teams and is responsible for recruiting clients. This involves ~20 h per team per faculty each year [38]. At Harvey Mudd College, a faculty director oversees the program and is responsible for recruiting projects, in exchange for teaching credit. In addition, each project's faculty advisor receives teaching credit for supervising a project. In the Stanford-Eindhoven program, one project entails about 250 h of faculty time because the faculty recruit the projects, manage the international logistics, as well as mentor the teams [48].

Duration of Projects

The majority of student field projects documented in the literature take place within a single semester, usually the final semester of the students' degree program [20,23,37,40,43,44,50]. The capstone project at the University of Dayton involves one credit hour in the fall semester for problem scoping, and five credit hours (or nearly two full courses) in the spring semester for completing the project. In between the fall and spring semesters, clients have ample time to gather needed data and prepare confidentiality agreements [38]. At Harvey Mudd College, the senior capstone spans both the semesters of the senior year and counts as a full course in each semester [39]. At the University of Alabama Productivity Center, projects range from short-term technical assistance projects to multiyear projects suitable for a PhD dissertation [46].

Team Structure

Most teams described in the literature have three to five student members [37–41,45,53], with [45] mentioning individual projects for MBA students and [5] describing teams as large as six to accommodate the large number of students in the bachelors degree program. Overall program sizes vary considerably. The Math Clinic program at Harvey Mudd College has 3–4 projects running annually [39], while the US Air Force Academy runs 8–10 projects each year [37], and the Indiana University South Bend had 70 OM field projects running during the 1998–1999 academic year, between a junior-level operations management course and an MBA-level operations management course [45]. The Alabama Productivity Center has funding for 25–30 students at a time and has participated in over 1300 projects over 25 years [46]. Most teams have a faculty mentor involved, and some also have professional engineering staff [46]. One of the team members (student, faculty, or staff) typically acts as a project manager. Teams can consist of students from a single major or can be interdisciplinary across several majors, depending on the needs of the project.

In some universities, students are assigned to teams by faculty, who sometimes take student preferences into consideration [39]. In other universities where field projects are not graduation requirements, students might have to interview in order to participate [48,50]. At the US Air Force Academy, clients compete for student interest by giving presentations on the first day of the course; students then vie for a client's attention to be the chosen team for the project. Teams are assigned to projects based on client and team preferences. When students choose their own project, there is a greater chance that the student will remain interested and engaged throughout [37]. On the other hand, assigning students to teams offers a greater growth opportunity for learning effective team dynamics, mimicking reality where one cannot always choose one's coworkers.

Another variable in the structure of these student field projects is the time commitment made by the students to the project during

the semester. Some programs require students to keep track of their billable hours [37,54]. At the Air Force Academy, each student spends ~4 h per week on the project [37]. At the University of Sydney, each student is expected to spend 7.5 h per week, but half of that time is spent in class [40]. Time commitments at the University of Dayton and Harvey Mudd College are larger, on the order of 8–10 h per week per student, amounting to ~500 person-hours per one-semester project involving teams of three at Dayton and 1200 person-hours per two-semester project involving teams of four at Harvey Mudd College [38,39].

Interactions between Teams and Client

Without regular interactions between the team and client, it is very easy for the students to pursue their own model without knowing whether or not it meets the client's objectives [39,46,50]. Therefore, a director of a student field projects program needs an assurance up front that the client will be committed to the project so that the students receive the guidance they need to solve the client's problem, not their own problem [50].

This guidance typically takes several forms. At a minimum, projects usually start with a kickoff event in which clients not just describe their desired outcomes of the project but also explain to the students the industry-specific context in which the project will be conducted and provide students the opportunity to brainstorm and ask questions [23,39,48]. Of the student field projects discussed in the literature, regular meetings with clients are also a common component, face-to-face if the client is local and via regular teleconference or occasional site visit if not [37–39,50]. These regular meetings serve to keep the client apprised of the progress being made by the team and to ensure that the project is not proceeding down an unfruitful path. In addition, most projects also require the client to respond promptly to questions and requests for data and information that can arise ad hoc. This communication typically takes place via e-mail. If the client is not committed to communicating regularly and responding to questions and requests in a timely fashion,

the project will be delayed [38]. Indeed, this can make or break a project, but clients do not always understand how critical this can be. The most successful projects are those with active and dedicated clients.

There is a delicate balance, however, between encouraging students to communicate regularly with the client and avoiding excessive demands on the client's time. One option is to appoint a team leader to manage all communications with the client. In addition, there are often library resources and the expertise of other faculty at the university that can be leveraged to provide the team with necessary background information without burdening the client.

Deliverables

Nearly all student field projects described in the literature require a written report at the end of the project that is given to the client. Several programs also require oral presentations before an audience of classmates, faculty, clients, and occasionally, outside reviewers [5,23,30,37,39,50,52]. In these oral and written reports, the students must communicate appropriately for the audience. Often, the clients are nontechnical or experts in different technical domains than ORMS [37,39]. Borrelli [39] describes Projects Day at Harvey Mudd College, where the entire campus and representatives from the ~40 clients watch a series of presentations and poster sessions given by the student teams. Other deliverables can include software and collected data that can help the client implement the project.

Gene Woolsey, a famous practitioner of OR, wrote "It is easier to do the math correctly (which requires no politics) than to get the method implemented (which always requires politics)," [55]. Implementing the results of an OR project can require several months or years of shepherding, as well as the full commitment of the sponsor to the outcomes of the project. Therefore, despite the potential educational benefits of involving students in this process, most of the student field project programs described in the literature omit the implementation phase. However, the MBA course described in Ref. 53 expects students to have a successful

implementation of the methodology within one year of the course. Thus, a deliverable is not just a report of recommendations; the students are also expected to help the client shepherd the project through implementation (this is feasible in an environment where the part-time students are still working full time in the organization in which the project is conducted). They report that many projects are implemented immediately, and only a few have little chance of ever being implemented.

Grading

In courses where a field project is only one component of the course grade, in addition to assignments and examinations, the literature suggests the project should count for 10–25% for undergraduate students and 15–30% for graduate students [30,44,45,52], with the difference attributed to the greater maturity and independence of graduate students.

Regardless of the weight of the project in the course grade, projects can be graded based on technical content, business content, the team's communication skills, project management, business outcomes, peer evaluations, as well as client evaluations [43,47]. Such evaluations can be used not only to assess the team's performance at the end of the project but also to provide formative feedback that can help the team during the project.

At Harvey Mudd College, each student submits a confidential self-evaluation and peer evaluation of each team member. The criteria used in this evaluation include numerical scores on cooperativeness, initiative, quality of technical work, quality of documentation, oral communication, reliability and follow-through on commitments, creation of useful results, creativity, promptness, and preparation. In addition, each student writes a narrative about the salient contributions, strengths, and weaknesses of each team member. These narratives typically convey useful behind-the-scenes information about the relative contributions of each student that might not already be apparent to the faculty advisor. This permits the faculty advisor to give a different grade

to each student and discourages students from “free-riding.”

Team presentations can also be evaluated by student peers, other faculty, and the clients to assess both the technical merits of the project and the team’s communication skills. Presentation rubric items can include clarity, effective use of technology, and appropriate technical content for intended audience. Additional free comments can be solicited to suggest improvements to both the presentation style and the technical approach to the project.

Because many student field project programs operate as consultancies (with students receiving academic credit, or being paid, or having the option to choose, as in Ref. 54), some programs have created policies for terminating unproductive members of a team. At the University of North Texas, where students receive academic credit for their work, a team has recourse to “fire” an unproductive student, provided they prepare sufficient documentation demonstrating the grounds for termination as would be required in a business environment [43]. In consultancies where students are paid rather than receiving academic credit, the precedent for terminating employment is more straightforward [43,54].

Institutionalizing These Experiences

The long-term success and continuity of these student field project programs can depend on individual personalities who spearhead the programs as well as institutional infrastructure [41], raising the question of what will happen when that person goes on sabbatical or leaves the university. Clearly, the program needs to be fully embraced by the department and the university administration. In a traditional publish-or-perish environment, Miller [46] indicates that a consultancy might not be taken seriously unless it is led by a respected faculty member with research credibility, rather than an administrator. At undergraduate colleges, such as the US Air Force Academy and Harvey Mudd College, there is greater hope for the longevity of a student-centered program. Indeed at Harvey Mudd College, nearly three-quarters of the student body participates in the field project

capstone program, across several majors [39]; its broad institutional support has no doubt played a major role in its success for over fifty years.

Miller [46] makes an important point that there is a risk when a program becomes institutionalized to the point of being required by its university to be self-funded. At that point, the program faces an urgent need to attract billable work, even if the pedagogical benefits of that work are insignificant. The program might need to turn down a challenging and interesting project from a nonprofit organization in favor of technical drudgery that is well funded by the client. Miller argues that if the school at least partially subsidizes the program then the program can focus on finding meaningful projects.

Challenges

One of the greatest obstacles to running a field project program is limited faculty time. Recruiting clients can take considerable effort. If the field projects are instituted as a supplement to an existing curriculum then there is less pressure to recruit projects than if the project is a graduation requirement [36]. The recruiting barrier becomes greater if the program needs to charge fees to cover costs, unless the program has a track record of success. However, as Wouters and van Donselaar [36] point out, with fees come the expectation of satisfying the client, to the possible detriment of the educational objectives of the program. In addition, considerable faculty time is needed to advise the teams in a meaningful way. Gorman [38] reports that feedback on the field experience from student interviews focused on improved selection and scoping of projects and more structured feedback and formal coaching for the teams, the very aspects that are the most time consuming for faculty. As described earlier, some schools count these programs toward a faculty member’s teaching load, but others do not. Failure to compensate faculty members for their time can result in a program structure that is convenient but perhaps not optimal for student learning. Lastly, advising such projects can bring faculty members out of their comfort zone, in that they must

relinquish some control over the outcome of a course or project [43].

In addition to those barriers, occasionally, projects are a disappointment to the student teams and the clients. Gorman [38] gives several reasons why a project might fail: the client's representative could lose her or his job or change positions; the students might procrastinate and try to complete the project at the last minute; the client might delay in giving the team necessary data; the project may turn out to be a "toy problem" that is not of any value to the client; the project might turn out to be significantly harder than anticipated; or the team might have difficulty in framing the problem.

Lastly, at many research universities, a tension can exist between conducting "applied research," such as typically arises from field projects, and more theoretical "basic research," that yields publications and grant funding. In one of the earlier discussions of ORMS education, Ackoff wrote of field projects: "In my opinion such involvement of students in research under faculty guidance is the most important instrument of education in the Management Sciences. Such activities do not preclude basic research; to the contrary, they stimulate it. No real problem worth solving can be solved without some basic research. Therefore the engagement of faculty and students on real problems yields basic research problems whose solutions are of practical significance," (Ref. 56, p. B4).

These potential challenges should not be treated as excuses for not pursuing field projects. As discussed earlier, there are myriad educational, academic, and institutional benefits to such projects.

CONCLUSIONS

Smith cautions: "It would be a mistake to sacrifice theoretical skills, which a university best teaches, for practical skills, which practice best teaches," (Ref. 57, p. 925). The project-based pedagogy described above should not be seen as a substitute for technical training in the mathematical methodology of ORMS. However, if practice

best teaches practical skills, as Smith suggests, then the above should provide inspiration for how to incorporate actual practice into ORMS education.

As described earlier, several institutions have begun assessing their project-based educational programs and comparing student outcomes to those achieved in more traditional courses. The early results are encouraging, suggesting that students who have completed a project-based course achieve better exam scores, better job placement and deeper satisfaction with the course than those who have not. However, more studies are needed to better assess the ability of project-based education to achieve specific learning objectives and long-term retention of ORMS skills.

PROSPECT THEORY

ANDREW CHIU
GEORGE WU
University of Chicago Booth
School of Business,
Center for Decision
Research, Chicago, Illinois

Prospect theory is a descriptive theory of how people make choices that involve risk. The theory was developed by psychologists Kahneman and Tversky in 1979 [1]. In 2002, Kahneman was awarded the Nobel Prize in Economics, partially due to prospect theory's enormous influence on economics and other social sciences, and partially due to Kahneman and Tversky's research on heuristics and biases [2]. (The Nobel Prize cannot be awarded posthumously, and Tversky died in 1996.) Prospect theory challenged the traditional view in economics that decision makers are rational and, in particular, expected utility maximizers. However, prospect theory's reach has not been limited to economics—the theory has been influential in understanding a wide variety of real-world phenomena, in fields ranging from business, law, and medicine to political science and public policy.

Most real-world decisions must be made without full knowledge of what will transpire in the future. Consider, for example, an oil and gas company debating whether to drill for oil, an investor deciding whether to purchase Microsoft stock, or a family choosing whether to vacation in Chicago in May. These decisions would be straightforward if the decision makers could predict the future with certainty. But people are not clairvoyant. There may or may not be oil in the ground. Investing in Microsoft stock may increase your wealth, but you may also end up losing a sizable portion of your initial investment. Weather in Chicago in May could be glorious or unbearable.

The objective of prospect theory is to describe how people make decisions when there is uncertainty about the consequences of their choices. Decision theorists distinguish between *decision under risk*, situations in which the likelihood of events are known or objective (such as a spin of a roulette wheel), and *decision under uncertainty*, situations in which the decision maker must assess the probability of the uncertain events and hence the likelihood of events are subjective (such as the outcome of a sports game) [3]. Although prospect theory applies to both risk and uncertainty, we will focus here on risk for simplicity.

EXPECTED UTILITY THEORY

Before prospect theory, the dominant theory of how people choose among risky alternatives was expected utility theory. This theory was originally proposed by Bernoulli in 1738 [4] and was formalized by von Neumann and Morgenstern in 1947 [5]. von Neumann and Morgenstern proposed a set of axioms, or basic conditions, that are necessary and sufficient for expected utility. Expected utility theory is a standard building block of modern economic theory [6,7]. It is regarded to be rational to be an expected utility maximizer, as this theory is based on compelling axioms about how people *should* behave [8].

Expected utility theory posits that decision makers choose the prospect that maximizes their expected (or average) utility. More formally, consider a risky prospect, $P = (p_1, x_1; \dots; p_i, x_i; \dots; p_n, x_n)$, that offers outcome x_i with probability p_i , where $\sum p_i = 1$.

According to expected utility, the prospect P is evaluated as $U(P) = \sum_{i=1}^n p_i u(x_i)$, with decision makers choosing the prospect with the highest expected utility.

Under expected utility, risk preferences are completely captured by the shape of the utility function. Decision makers are risk averse if $U(x)$ is concave, and risk seeking

if $U(x)$ is convex, with most classical economic theory based on the tenet that decisions makers are risk averse. One standard interpretation for risk aversion is that the usefulness of an additional dollar decreases as a person gets wealthier, a principle known as *diminishing marginal utility* [9]. A utility function that exhibits diminishing marginal utility is concave, and hence the decision maker is risk averse.

PROSPECT THEORY

Kahneman and Tversky showed that decision makers are not rational as required by expected utility theory. The theory has been successful in making this point, largely because the theory consists of three parts that are individually attractive and work together well. First, Kahneman and Tversky produced a number of intuitive and elegant empirical demonstrations that were at odds with expected utility theory. Second, they proposed a mathematical model that could explain and organize these violations. Finally, they posited some psychological principles that suggest how people evaluate the alternatives they face. We begin by reviewing the primary empirical demonstrations that challenged the standard theory that decision makers are rational. We then describe the pieces of the mathematical model used to organize these violations. Throughout, we discuss how the psychological principles provide insight into these empirical demonstrations and review these principles at the end of this section.

Empirical Demonstrations

Fourfold Pattern of Risk Attitudes. Standard economic theory assumes that individuals are *risk averse*. Consider a lottery that offers a 50% chance to win \$1000 and a 50% chance to win \$0. The expected value of this lottery is $\$500 (0.5 \times \$1000 + 0.5 \times \$0)$. A risk-averse individual prefers winning the expected value of this lottery, \$500, for certain, to the lottery itself. Indeed, surveys show that the vast majority of people are risk averse for this choice.

But individuals are not universally risk averse. They dislike risk in some situations, while liking risk in others. For example, lotteries and casinos are billion-dollar industries in the United States. Many individuals purchase lottery tickets, even though the expected value of a state lottery ticket is often as little as half the price of the lottery ticket [10].

Kahneman and Tversky demonstrated that the purchase of lottery tickets is not an isolated example of risk-seeking behavior. They documented a pattern that has become known as the *fourfold pattern of risk attitudes* [11]. Individuals are risk averse for most gains, but risk seeking for most losses. As previously mentioned, most people would choose \$500 for sure over a lottery that offered them an equal chance at \$1000 or \$0. On the other hand, the same person typically prefers an even chance at losing \$0 or losing \$1000 to losing \$500 for sure. This pattern, however, switches when probabilities are small. In this case, decision makers are risk seeking for gains, and risk averse for losses. Consider a choice between winning \$1 for sure and a prospect that offered a 1% chance at winning \$100. Gambling in this case seems pretty reasonable. After all, \$1 is not much money, and the lottery offers some chance at winning a sizable amount of cash. The purchase of a lottery ticket is indeed an example of risk seeking for small probability gains. However, preferences reverse when we change “winning” to “losing” in the above example. Now, the typical preference is for losing \$1 for sure over taking a prospect in which there is a 1% chance of losing \$100. The attractiveness of insurance provides an example of risk aversion for small probability losses. In sum, the fourfold pattern of risk preferences is risk aversion for medium to large probability gains, risk seeking for small probability gains, risk seeking for medium to large probability losses, and risk aversion for small probability losses. This pattern is often called the *reflection effect*, because preferences flip or “reflect” when outcomes are changed from gains to losses.

Framing. Expected utility theory assumes that preferences between prospects do not depend on the manner in which they are described. For example, \$20 should be viewed the same whether you are given a single \$20 bill, two \$10 bills, or 20 singles. This compelling principle is known as the *invariance assumption*. However, prospect theory demonstrates that the same options can be framed in different ways to produce dramatically different preferences. In other words, our choices do not always obey the invariance assumption.

To illustrate, consider the following two-choice situations:

- In situation 1, you are first given \$1000. You must now choose between two options. If you choose *A*, you will receive an additional \$500 for sure. If you choose *B*, there is an equal chance that you will receive either an additional \$1000 or nothing.
- Now consider situation 2; this time you are first given \$2000. Again, there are two options. Perhaps you would like *C*, a sure loss of \$500? Or, maybe you would prefer *D*, a 50% chance at losing \$1000 and a 50% chance at losing \$0?

When confronted with situation 1, most people prefer *A*, the sure \$500, to the gamble *B*. On the other hand, when posed with a choice between *C* and *D*, most choose *D*, the uncertain loss, over the sure loss *C*. While both choices seem reasonable in isolation, situations 1 and 2 are identical in terms of final consequences, reducing to a choice between \$1500 for sure (*A* and *C*) and a lottery that offers an even chance at \$1000 or \$2000 (*B* and *D*).

The standard preferences described above violate the invariance assumption invoked by expected utility. However, they are consistent with the risk attitudes revealed by the fourfold pattern of risk attitudes. When the problem is framed as a gain (situation 1), people are usually risk averse. But when the problem is framed as a loss (situation 2), people tend to be risk seeking.

Aversion to Losses. Expected utility theory assumes that choices only reflect final outcomes. For example, if one were the beneficiary of a \$100 check, but also received a \$100 speeding ticket, these two events would offset one another in monetary terms. However, Kahneman and Tversky demonstrated that individuals tend to dislike losses much more than they like gains. Thus, the two events do not offset one another in psychological terms. The \$100 check makes you happy, to be sure. But, your pleasurable feelings for the check pale in comparison with the pain you feel when you are reminded about your \$100 speeding ticket. This dislike of losses is known as *loss aversion*. Put simply, losses loom larger than gains.

To illustrate loss aversion, consider a gamble in which you may lose \$1000 or gain \$1100 with equal chance. Although the expected value of this gamble is positive, most people find this prospect unappealing. The potential loss of \$1000 cannot be offset by the potential gain of \$1100. In order to make this gamble attractive, the gain has to be increased considerably, to about \$2000. In other words, roughly speaking, the pain of a loss is about twice as much as the pleasure from a comparably sized gain [12].

Common-Consequence Effect. Suppose that you are faced with the following choice. If you choose *A*, you receive \$200 with 10% chance. If you choose *B*, you receive \$100 with 20% chance. Next, imagine that we improve both options by adding to each a 10% chance of receiving \$1000. Now if you choose *A*, you receive \$200 with 10% chance, \$1000 with 10% chance, and \$0 with 80% chance. If you choose *B*, you receive \$100 with 20% chance, \$1000 with 10% chance, and \$0 with 70% chance. It seems reasonable that your choices in these two situations be identical, that is, unaffected by the additional chance at receiving \$1000. Since both of the second options have a 10% chance of receiving \$1000, this common consequence is irrelevant for this choice. Expected utility theory assumes this principle—adding a common consequence to two prospects should not change which alternative the decision maker

prefers. This principle is known as the *independence axiom* [13,14].

Kahneman and Tversky documented a violation of this principle. Consider the following two choices:

Situation 1

- option *A* offers a 33% chance at \$2500 and a 67% chance at \$0;
- option *B* offers a 34% chance at \$2400 and a 66% chance at \$0.

Situation 2

- option *C* offers a 33% chance at \$2500, a 66% chance at \$2400, and a 1% chance at \$0;
- option *D* offers \$2400 for sure.

Most people prefer *A* to *B*, arguing that 33% and 34% seem about the same, but \$2500 is clearly better than \$2400. On the other hand, people like *D* over *C*, reasoning that it is not worth taking a chance with *C* since *D* has a sure chance of winning a good amount of money. To see that this pattern of choices violates the independence axiom and hence is inconsistent with expected utility, note that situation 2 is created from situation 1 by adding a common consequence to both *A* and *B*: a 66% chance at \$2400.

This problem illustrates the strong preference for certainty over uncertainty. Indeed, this example has been termed the *certainty effect*. Adding a 66% chance at \$2400 to *B*, a 34% chance at \$2400, is particularly attractive, because it changes the prospect from possible to certain. On the other hand, for option *A*, the additional 66% chance at \$2400 increases the chance of winning from 33% to 99%, or from probable to more probable.

This demonstration is also called the *common-consequence effect*, because adding a common consequence to two options changes preferences, contrary to expected utility theory [15]. Indeed, a variant of this problem posited by the French economist Maurice Allais was one of the earliest challenges to the descriptive validity of expected utility [16]. Allais' challenge, which has become known as the *Allais Paradox*, consisted of two pairs of gambles. The first involved a choice between either (*A*) \$1 million for

sure or (*B*) a 0.10 chance at \$5 million, a 0.89 chance at \$1 million, and 0.01 chance at \$0, whereas the second was a choice between (*C*) a 0.11 chance at \$1 million (and a 0.89 chance at \$0) and (*D*) a 0.10 chance at \$5 million (and a 0.90 chance at \$0). Most people prefer *A* and *D*, a pattern that contradicts expected utility. Under expected utility theory, a choice of *A* over *B* implies that $0.11u(1) > 0.10u(5) + 0.01u(0)$, whereas a preference for *D* over *C* implies the opposite inequality, $0.10u(5) + 0.01u(0) > 0.11u(1)$.

The Prospect Theory Model

Prospect theory offered a rich set of empirical challenges to expected utility theory, including the fourfold pattern of risk attitudes, framing effects, aversion to losses, and the common-consequence effect. These demonstrations are robust, attractive, and intuitive. But do these demonstrations inform us about how individuals make decisions that involve risk in general? Kahneman and Tversky proposed a model for organizing the empirical demonstrations described above and making more accurate predictions about how individuals would behave in other choice situations.

Like expected utility theory, prospect theory assumes that individuals evaluate each alternative and then choose the alternative with the highest subjective valuation. However, prospect theory differs from expected utility theory in two substantive ways. Suppose a decision maker might choose an alternative that offers a p chance at outcome x . Expected utility theory assumes that the utility of this alternative is $pu(x)$. Prospect theory, like expected utility, assumes that the decision maker evaluates the x that he/she might get and the p chance at winning, and then combines these two evaluations together. However, the valuation of outcomes is governed by the *value function*, $v(x)$, and the valuation of the probabilities is governed by the *probability weighting function*, $\pi(p)$, and thus the value of this alternative is given by $\pi(p)v(x)$. [The valuation of more complicated alternatives with more than one nonzero outcome follows a revision of prospect theory, *cumulative prospect theory* [11].] These two pieces are described below.

Value Function. The prospect theory value function, $v(x)$, captures an individual's subjective perception of a particular outcome (Fig. 1). Prospect theory assumes that outcomes are coded as gains and losses, or outcomes above and below a reference point, and the value function captures how much better one gain is than another gain, how much worse one loss is than another loss, or alternatively how a particular loss compares with a gain of the same magnitude.

Three psychological principles constrain the shape of the value function. The first principle, *reference dependence*, suggests that outcomes are viewed relative to a reference point and hence coded as gains or losses. A \$10,000 bonus is seen differently if an employee is expecting a \$5000 bonus or a \$15,000 bonus. The bonus is seen as a \$5000 gain in the first case, but a \$5000 loss in the second case.

The second principle, *diminishing sensitivity*, borrows from research on the psychophysics of perception. Research has shown that an individual is highly likely to discriminate between a 2 and 3 kg weight, but not very likely to notice the difference between 22 and 23 kg weights [17]. Analogous findings appear in tasks ranging from the perception of line lengths to the perception of temperature. Prospect theory thus suggests that changes in value have a greater impact near the reference point than away from the reference point. Thus, there is a big difference between a \$100 gain and a \$200 gain, but a much smaller difference between gains of \$1100 and \$1200. Similarly, a loss of \$100 seems quite distinct from a loss of \$200, but losses of \$1100 and \$1200 seem pretty similar.

The principle of diminishing sensitivity away from the reference point is consistent with the reflection effect described above. Most people would choose \$500 for sure over an even chance at winning \$1000 or winning \$0. Diminishing sensitivity suggests that the first \$500 is more pleasurable than the second \$500. When this choice is changed to losses, however, preferences switch. The majority of individuals prefers an even chance at losing \$1000 or losing \$0 to losing \$500 for sure. This

Figure 1. A typical prospect theory value function, $v(x)$, which is concave for gains and convex for losses (and thus consistent with the principle of diminishing sensitivity) and is steeper for losses than gains (and thus exhibits loss aversion).

preference is also consistent with diminishing sensitivity, because the first \$500 loss is much more painful than the second \$500 loss. Thus, the value function in Fig. 1 is concave for gains and convex for losses.

The third psychological principle underlying the value function is *loss aversion*. Recall that losses loom larger than gains. A loss of \$100 seems much more painful than a gain of \$100 seems pleasurable. Most people dislike a prospect that gives an equal chance at winning \$1000 or losing \$1000. These two examples are captured by a value function that is steeper for losses than gains ($-v(-x) > v(x)$), as is depicted in the value function in Fig. 1.

Probability Weighting Function. Prospect theory assumes that individuals do not weigh outcomes by their probability, as in expected utility theory, but by some distortion of probabilities. This distortion of probability is captured by prospect theory's probability weighting function, $\pi(p)$ (Fig. 2). Interestingly, the psychology governing the distortion of probability involves two of the three principles used to understand the value function, reference dependence and diminishing sensitivity away from a reference point. For probability, there are two obvious

Figure 2. A typical prospect theory probability weighting function, $\pi(p)$, which is concave for small probabilities and convex for medium to large probabilities (and thus consistent with the principle of diminishing sensitivity).

reference points, certainty and impossibility, or 100% chance and 0% chance. The distortion of probability shown in the probability weighting function captures the diminishing sensitivity away from these two reference points. People are most sensitive to changes in probability when they are near 0% or 100% than when the change applies to intermediate probabilities. Consider adding a chance to win a large prize, such as a new car. Which of the following appears to be the least significant increase: increasing your chance of winning from 0% to 1%, from 33% to 34%, or from 99% to 100%? Most people regard the change from 0% to 1% as significant, because it changes the chance of winning from impossible to possible [18]. The change from 99% to 100%, too, seems noteworthy, because it shifts the odds from likely to certain. In contrast, the change from 33% to 34% seems negligible. Put simply, there is a categorical difference between impossible and possible or between likely and certain, but the difference between possible and slightly more possible is a matter of degree. The probability weighting function in Fig. 2 exhibits diminishing sensitivity: $\pi(0.01) - \pi(0) > \pi(0.34) - \pi(0.33)$ and $\pi(1) - \pi(0.99) > \pi(0.34) - \pi(0.33)$. The function is thus concave for small probabilities and convex for medium and large probabilities.

Diminishing sensitivity implies that low probabilities are typically given more weight than they would receive using expected utility. This overweighing is consistent with risk seeking for low probability gains (such as lottery tickets) and risk aversion for low probability losses (such as insurance). Medium to high probabilities are typically given less weight than they would receive using expected value. Such underweighing is consistent with risk aversion for medium to high probability gains, and risk seeking for medium to high probability losses. The probability weighting function also helps us understand the common-consequence effect described above. In the first choice, the probabilities of winning a prize are 33% and 34%, whereas the probabilities of winning with the second choice are 99% and 100%. The probability weighting function suggests that the first difference is trivial (thus decision makers look at outcomes to make this choice), whereas the second difference is consequential (and thus sufficient to drive the decision).

Psychological Principles

Prospect theory invokes three psychological principles: reference dependence, diminishing sensitivity, and loss aversion. The first two principles produce the characteristic form of the value function and the probability weighting function shown in Figs 1 and 2. For the value function, outcomes are viewed relative to a reference point, with outcomes above the reference point coded as gains and outcomes below the reference point coded as losses. The valuation of both gains and losses exhibits diminishing sensitivity away from the reference point. For the probability weighting function, probabilities are viewed relative to the reference points of impossibility (0) and certainty [1]. Changes away from these two reference points also exhibit diminishing sensitivity.

APPLICATIONS

Prospect theory has been useful for understanding real-world phenomena in a variety of domains. A few applications are discussed

below to provide a flavor of the broad reach the theory has had. For a description of other applications, see Ref. 19.

Mental Accounting

Although prospect theory was developed to explain how people make choices involving risk, the principles of prospect theory have been used to understand how people choose among certain alternatives as well. One influential application of prospect theory is known as *mental accounting* [20,21]. Mental accounting is a theory of how individuals and households make consumer and financial decisions. Most of the implications of mental accounting follow from the shape of prospect theory's value function.

Mental accounting suggests that people prefer to segregate gains and aggregate losses. Consider, for example, two pleasurable outcomes, a \$100 check from your aunt and \$50 won in a school raffle. Most people find it more enjoyable to view these outcomes separately, \$100 *plus* \$50, than together, \$150. The attractiveness of segregating gains follows from the shape of the value function and the psychological principle of diminishing sensitivity away from the reference point of zero. Next consider two painful outcomes, a \$100 speeding ticket and a \$150 tax liability. It seems clear that aggregating the losses is a good idea psychologically. In other words, a loss of \$250 seems less painful than two separate losses of \$100 and \$150. Mental accounting suggests that aggregating losses is more attractive than segregating losses. This simple principle helps us understand a number of real-world phenomena, including the attractiveness of flat-rate pricing plans. Most people find it less painful to pay \$70 for a monthly health club membership than \$10 each time they work out [22].

Mental accounting also suggests that different ways of framing the same activity can be viewed very differently. Suppose that you have decided to purchase a new car for \$22,000 and are contemplating purchasing a stereo upgrade. A car salesperson can frame the stereo as a \$300 purchase or an increase in the total price of the new car from \$22,000

to \$22,300. It is clear that the salesperson will be more effective at convincing you to purchase the upgrade if he/she frames the upgrade as an increase in price. Again, the principle at work is diminishing sensitivity of the value function.

Consider one final example of mental accounting. Imagine that you can walk 10 minutes to save \$5. Would you do so? People give different answers if the purchase is a \$25 calculator or a \$125 jacket. A \$5 discount seems more significant when it is applied to the inexpensive calculator rather than the expensive jacket. Of course, this behavior is not rational, since the decision to walk 10 minutes boils down to a choice of whether walking 10 minutes is worth \$5.

Status Quo Bias

In many situations, the decision maker must decide whether to choose a particular alternative or stick with the status quo. However, the status quo is frequently chosen much more often than it should be if the evaluation of the alternative were made simply based on the positive and negative features of that alternative. One study found a strong status quo bias for the choice of automobile insurance plans. Prior to deregulation in the early 1990s, Pennsylvania had an expensive insurance plan that allowed a driver to sue another driver in many situations. New Jersey had a cheaper plan that permitted its driver to sue only in limited situations. As a result of deregulation, citizens of Pennsylvania were permitted to trade down to the cheaper plan, and people in New Jersey were allowed to trade up to the more expensive plan. Nevertheless, 75–80% of drivers stuck with their original plan [23].

How does prospect theory help us understand why people tend to prefer the status quo? When giving up the status quo for another alternative there are, typically, trade-offs to be made. An option will have advantages and disadvantages relative to the status quo. The advantages are likely to be perceived as gains relative to the status quo, with the disadvantages perceived as losses. Because of loss aversion, losses

appear more significant than gains of comparable magnitude. The principle that losses loom larger than gains explains why people have a tendency to remain at the status quo—a phenomenon known as the *status quo bias*.

A related demonstration, called the *endowment effect*, shows once again the asymmetry between losing and gaining [24]. In one study, half of the participants are given a lottery ticket and half of the participants are given \$2 [25]. In each case, the participants can keep what they were given or trade it for what the others were given. However, very few participants chose to switch. Those who were given lottery tickets largely stuck with the lottery tickets, but those who were given the cash mostly elected to keep the cash. Once again, prospect theory's principle of loss aversion can explain this phenomenon. When people are endowed with an item, it becomes the reference point from which other options are evaluated. Since losses loom larger than gains, giving up an item that one possesses is perceived as more painful than acquiring an item of comparable magnitude that one does not already possess.

Other Applications

Prospect theory provides insights into numerous other real-world decisions. We sketch a few applications below to give a flavor of the power of prospect theory. First, in horse track betting, favorites are usually underbet, and longshots are typically overbet [26]. This behavior can be explained by the probability weighting function. Second, consider an investor who bought two stocks at \$50. One has increased in value to \$75, and the other has fallen in price to \$25. If the investor has to sell one stock, which would he/she sell? Financial economists have shown that investors overwhelmingly sell the winner rather than the loser [27]. The *disposition effect* suggests that selling the loser is unattractive, because the investor must come to terms with his/her losses.

Finally, we consider choices of retirement plans. Employers often provide a default

plan, or a plan that will be chosen if the employee does not make a choice. This plan is often a sensible plan, but it is often chosen by the vast majority of employees, even when another plan might make more sense [28]. To see why prospect theory can explain this choice, we assume that the default plan is the reference point for evaluating another retirement plan. A second plan will be better on some dimensions and worse on other dimensions. Because of loss aversion, the dimensions on which the second plan is inferior loom large compared to the dimensions on which it is superior, providing a substantial advantage to the default plan.

COLLEEN F. MOORE
Department of Psychology, University
of Wisconsin-Madison, Madison,
Wisconsin

Risk perceptions refer to subjective judgments of risk that may involve both cognitions and emotions. Risk perceptions can be assessed in a variety of ways such as asking for estimates of the subjective probability and severity of an event, estimates of the risk of death or other negative outcomes, or ratings of the overall risk of an activity for a specific person, group of people, or the environment. Risk perceptions can be used as one predictor of public acceptance or opposition to new and existing technologies. Research in psychology has examined factors that influence or correlate with risk perceptions.

DEVIATIONS FROM NUMERICAL RISK ESTIMATES: PROBABILITY WEIGHTING, HEURISTICS, AND BIASES

It is well established that risk perceptions deviate from numerical risk estimates. One explanation for this is that subjective probability is nonlinearly related to numerical probability. Research has shown that people tend to overestimate small probabilities and underestimate large ones [1,2]. Kahneman and Tversky's [3] well-tested theory of decision making under risk, prospect theory, also reveals a tendency for people to over-weight small probabilities and under-weight larger ones. More recent research has found that whether people over- or under-weight small probabilities depends on the type of risky decision task employed. When presented with only descriptions of probabilities, people tend to over-weight small

probabilities, but when participants learn about probabilities through experience and feedback, they tend to under-weight small probabilities [4–6].

Apart from laboratory experiences with risk, experiences in the real world can also lead risk perceptions to deviate from numerical estimates through the availability heuristic. The availability heuristic says that people perceive events as more likely to occur if they are easier to bring to mind or imagine. According to the availability heuristic, risks that people have personally experienced, that are more vivid, and that receive more media coverage are judged as more prevalent relative to equally probable risks that are less available [7,8]. In addition, this heuristic can lead to what is called the *optimism bias*: people tend to judge themselves as less vulnerable to risks than others [9,10]. For example, if people hear news reports of others getting into car accidents, but they themselves have never gotten in one, they will perceive their personal risk as lower than others' risk [7].

BEYOND NUMERICAL RISK ESTIMATES: A PSYCHOMETRIC MODEL OF RISK PERCEPTION

Risk perception is not just determined by statistics and probabilities, but also by a number of qualitative factors related to the risks. Fischhoff and colleagues [11] first tested a psychometric model of risk perception and risk acceptability that examined several factors hypothesized to influence risk responses. Participants evaluated a wide range of technological and nontechnological risks in terms of their perceived risk, benefit, and acceptability. They also included variables to measure the degree to which the risks were voluntary, controllable, known, catastrophic, dreaded, and so on. A factor analysis of these variables revealed a two-dimensional model characterizing risk judgments that has been replicated

across many different groups of people [12]. One dimension is called *dread risk* and includes such factors as uncontrollable, dreaded, catastrophic, involuntary, inequitable, fatal, new, global, and not easily reduced. Risks found to be high on the dread dimension include nuclear weapons and reactors, radioactive waste, and DNA technology. Risks found to be low on dread include highly familiar technologies such as caffeine, aspirin, and power mowers. The second dimension is the known-unknown spectrum, characterized at one extreme by risks that are not understood by science or that are unobservable, new, and delayed in their effects. Risks found to be high in this dimension include DNA technology, electric fields, and nitrogen fertilizers; risks found to be low on this dimension include handguns, dynamite, and auto accidents. Nonexperts' risk perceptions are correlated with these two dimensions, especially the dread dimension. Technologies and activities that are rated more highly on the dread and unknown dimensions are perceived as riskier and less acceptable than those rated lower on these dimensions.

This model has been replicated in many different cultures [13–16]. In addition, the dread and knowledge dimensions have been identified in case studies of individuals encountering real risk events [17].

KNOWLEDGE: EXPERTS' VERSUS NONEXPERTS' RISK PERCEPTIONS

As knowledge about risks plays an important role in the psychometric model of risk, it makes sense that differences in knowledge would also influence risk estimates. Slovic [12] reported that experts' risk perceptions were not influenced by their ratings on the dread and unknown dimensions of risk, but instead their risk perceptions correlated with estimates of annual fatalities. Indeed, nonexperts can produce estimates of fatalities with rank-order similar to experts' technical estimates [12,18], nevertheless, their risk perceptions seem to be not entirely based on fatality estimates. Sjöberg [19] categorized comparisons of expert and nonexpert

risk perceptions into three types. First, there are similarities between experts and nonexperts when estimating fatalities caused by common, well-known risks. Second, nonexperts' risk perceptions are lower than experts' for some hazards. This seems to occur when individuals believe that they personally have control over a risk, and so, whereas risks to others might be high, risks to themselves are perceived to be low. Examples of these risks are smoking, drinking, driving, and adventure sports. Third, sometimes experts estimate risks to be lower than nonexperts do. This occurs most commonly for complex technological systems. The most extreme example is with nuclear power, where nonexperts perceive risk to be much higher than experts [12,20,21].

The difference in risk perceptions for complex technologies has been the most commonly studied. Several factors from the psychometric model could partially account for these differences, including differences between experts and nonexperts in familiarity, knowledge, and perceived controllability of technological risks. One study found that experts' risk judgments for biotechnology in food and medicine were higher than nonexperts', and that whether the applications of biotechnology were viewed as harmful, beneficial, unknown to science, and new partially accounted for the differences between experts' and nonexperts' risk perceptions [22].

A review of studies comparing risk perceptions made by experts and nonexperts revealed that differences in risk perceptions may also be due to socio-demographic differences between the groups, in terms of gender, education, age, and income [23]. Data on socio-demographic differences between expert and nonexpert samples is scarce in past studies and few included these characteristics in predictive models. But when reported, it seems that expert samples are more likely to be male, older, more highly educated, and wealthier. Some of these characteristics are predictive of lower risk perceptions, as discussed later.

TRUST AND CREDIBILITY

Having less knowledge about a technology or scientific process implies that nonexperts have to rely more on getting risk information from institutions and organizations that manage risks and communicate risks to the public. There is evidence that the public's perceptions of risk are related to whether they view these sources of risk information and policy as credible and trustworthy [24–28]. One study showed that greater trust in companies and universities that are involved in gene technology predicted lower perceptions of risks, higher perceptions of benefits, and greater acceptance of the technology [25]. In another study, participants who felt that authorities shared their values in public health and information policy were more trusting of the authorities, and this trust predicted lower risk perceptions of a cancer cluster [26].

The effect of trust and credibility on risk perceptions can also vary depending on the agency, authority, or institution involved [22,29]. Trust tends to be highest for research institutes, environmental groups, and consumer groups. Government agencies and political organizations are trusted less, and industry is the least trusted source of information about risks. However, these differences can vary somewhat depending on the nationality of the participants [29]. For example, in Italy and the United Kingdom, the government is perceived to be almost as equally trustworthy as consumer groups, whereas in Germany, the government is perceived as much closer in trustworthiness to industry.

A survey of New York residents about local environmental risks employed a measure of credibility developed by Meyer [30] that included five factors: trust, accuracy, fairness, completeness, and bias [24]. Lower ratings of credibility of the state government and the offending industry predicted higher risk perceptions; however, perceived credibility of the local newspaper did not predict risk perceptions. In another study, lower risk perceptions (pertaining to possible cancer clusters) were predicted by higher ratings of credibility for government and industry

sources of risk information but lower credibility ratings for citizen groups [28]. Also, perceiving government and industry sources as having higher credibility and citizen groups as having lower credibility predicted a reliance on heuristic (i.e., quicker and less effortful) processing of risk information, which, in turn, predicted lower risk perceptions. However, other research showed that attitudes toward risky technologies (in this case genetically modified food) can account for much greater variance in trust than the source of the risk information (industry, government, or consumer group) [29]. This suggests that risk perceptions may in fact influence trust. The direction of this relationship is impossible to untangle with correlational data.

A review of the literature concluded that there are three dimensions of trust that can be important for predicting risk perceptions: competence, care, and consensual values [31]. Competence refers to the fact that the credentials, knowledge, and experience of the agents assessing and managing the risk will predict how much they are trusted. According to the care dimension, people will trust a risk decision-making process more if they feel they have some control over or involvement in the process and ultimate decisions made, thus increasing procedural fairness, and if they are treated with respect and compassion. The values dimension stresses that people will trust risk assessors and managers more if they feel they share their values (e.g., cultural, political, and social values [32]).

Trust in institutions has also been shown to vary by gender, with women reporting lower levels of trust than men [25,26]. Differences in trust levels may partly explain gender and other individual differences (e.g., race, socioeconomic status) in risk perceptions [33].

INDIVIDUAL DIFFERENCES: RACE, GENDER, SOCIOECONOMIC STATUS

Many studies have shown gender differences in risk perceptions, with women showing higher risk perceptions than men [33–35]. Studies have also reported racial differences

with whites showing lower risk perceptions than nonwhites [33,36]. Interestingly, studies have shown what has been called a *white male* effect; that is, white males often have lower risk perceptions than white females, nonwhite males, and nonwhite females across a variety of different hazards, from smoking, to climate change, to air travel [33,37,38]. In one study, this effect was found to be driven by about 30% of the white male sample that had extremely low risk perceptions [33]. When compared to the rest of the sample, this group was found to have higher levels of education and income, more conservative political beliefs, and more trust in institutions and authorities. Another study showed that white men were more likely than women and nonwhite men to feel that they have control over health risks, that small risks can be imposed on people without their consent, and that the government should not be trusted to manage technological risks [37]. Differences in age, income, and education did not fully account for these gender, race, and “white male” effects.

Although differences in knowledge have been argued to be a reason for different risk perceptions between men and women, even in a sample of scientists, female scientists were shown to have higher perceptions of nuclear risks than male scientists [34]. There were also gender differences in attitudes about technology, the environment, and individual rights in this sample. For example, male scientists were more likely than female scientists to agree that existing technology can reduce risks from nuclear waste to acceptable levels, that the environment can be kept clean without requiring changes in lifestyle, and that risks can be imposed on people without their consent. Thus, there is more support for differences in attitudes between genders and races as explanations for differences in risk perceptions than there is support for differences in knowledge [35]. Specific perceptions of technological risk may reflect more general attitudes about technology, and trust in institutions as well as be influenced by perceived personal control over or vulnerability to risks.

Less research has specifically explored other demographic variables such as age, income, and education as predictors of risk perceptions. Effects of these variables on risk perceptions and attitudes have been found, but the small number of results does not seem to be entirely consistent [39,40].

PERCEPTIONS OF UNCERTAINTY AND RISK

Beliefs about the credibility of sources of risk information can also be influenced by the type of information that gets communicated. Uncertainty factors are almost always incorporated into formal risk assessments to account for what is unknown or for extrapolations [41], and as a result, a range of risk estimates might be reported including a best point estimate and an interval around that estimate. Research has shown that when uncertainty is communicated via interval estimates it can lead many people to perceive that the source of the risk information is more honest but less competent [42,43].

How does uncertainty about risk estimates affect risk perceptions? Research has shown that uncertainty can increase perceptions of risk. For example, when a range of risk estimates was presented, more people believed the true risk was at the higher end of the interval rather than the lower end [42–44]. Other research has found only small increases or no increase in risk perceptions due to uncertainty [45,46]. Uncertainty might increase risk perceptions because people tend to imagine the worst-case scenario [43–45] or because uncertainty alters perceptions of the scientists or institutions estimating the risks [42,43]. However, uncertainty could also potentially lead to lower risk perceptions for people who are motivated to perceive lower risks [47]. For example, smokers may be motivated to perceive lower risks from smoking in the face of uncertainty.

FAIRNESS, VALUES, ETHICAL CONSIDERATIONS

In perceptions of environmental and technological risks, often what matters more to

people than probabilities and statistics are issues of ethics such as justice and fairness in the distribution of risk burdens, informed consent to exposure, participation in the risk decision process, and duties to future generations [41,48–52]. For example, an analysis of letters of protest on the siting of nuclear waste facilities revealed that many of the arguments were about fairness, in terms of consent and unequal distribution of risk [52].

Several studies with survey data have found correlations between relevant moral issues and risk perceptions. The “dread” dimension of risk, which predicts risk perception and acceptability, includes the inequitable and involuntary components of risk that are related to the ethical issues of unequal distributions of risks and lack of informed consent to risk exposure [12]. The moral valuation of risks is a strong predictor (25% variance) of both the acceptability and perception of those risks [51,53,54]. Judgments of environmental injustice also predict higher perceived risk [55]. Finally, research showing a relationship between different value systems (e.g., cultural worldviews) and risk perceptions suggests that moral issues have the potential to influence risk perceptions by upsetting certain core values [56,57].

Two recent experimental studies seem to corroborate these correlational findings about the impact of ethical issues on risk perceptions. Providing information about the moral implications (for animals, the environment, and humans) of eating meat increased perceptions and reduced acceptability of the risks of meat consumption [58]. Support for a risk decision increased and risk perceptions decreased when the risk decision process included public involvement [59]. This effect may have occurred because people thought the decision-making process was more fair and more reflective of public values. In addition, public involvement may have led to a reframing of the risk from an involuntary risk imposed on the public to a voluntary risk agreed to by the public [59].

EMOTIONAL REACTIONS TO RISKS: RECENT THEORETICAL PERSPECTIVES

Feelings of trust, fairness, and dread can be seen as having emotional qualities, in addition to cognitive content. Research has begun to examine how emotional reactions to hazards influence risk perceptions. Some work on emotions and risk has examined the effect of anticipated emotions, that is emotions such as regret or pleasure that you would anticipate feeling after experiencing the outcome of a risky decision [60]. This research showed that 44–74% of the variance in people’s risk decisions can be explained by a preference for maximizing the subjective likelihood of experiencing positive anticipated emotions. Researchers have also made a distinction between anticipated emotions and emotions experienced during the risk decision-making process. Recent theoretical models of risk have emphasized the role of experienced emotions, and research has examined the effect of direct emotional reactions to risk information as inputs in risk judgments [61,62]. The focus of these models is the effect of emotional reactions on risk perceptions, but it is also understood that risk perceptions can influence emotional reactions as well.

It has been proposed that people rely on an “affect heuristic,” an easily accessible impression of how good or bad a hazard is, as an efficient cue for determining their risk perceptions [62,63]. Considering emotion as an important factor in risk perceptions can help explain some of the findings in the risk perception literature. For example, people are less sensitive to probabilities of risks when the risks are associated with emotionally laden images that trigger an affective response [64]. This is one explanation for why potentially catastrophic hazards with small probabilities (e.g., terrorist attacks, nuclear reactors), nonetheless, can be perceived as very risky. Some evidence for the role of emotion in risk perception also comes from neuroscience research, which has shown that damage to an area of the brain involved in emotion generation (ventromedial prefrontal cortex) hinders performance on risky decision tasks [65]. Current psychological theories of risk perception emphasize the importance

of both affective and cognitive evaluations of risk, and the interplay between these two processes [62,66].

CONCLUSION

Risk perception differs from numerical risk estimation and formal risk assessments because it is influenced by a wide array of psychological considerations such as trust, moral and social values, personal experience, and emotional reactions. Some variables that influence risk perceptions, especially ethical issues, trust, and future unknown outcomes, are very difficult to include in numerical risk assessments. For this reason, risk perceptions of members of the public sometimes add important information that is excluded from formal numerical risk assessments. In addition, risk communicators and managers must acknowledge and understand the role of psychological factors in risk perception in order to effectively gauge public responses to risks and design informative and effective risk messages and warnings.

INTRODUCTION

In the aftermath of the September 11 terrorist attacks and the dissemination of anthrax in 2001, the ability of the US health care system to provide an effective and coordinated response to mass casualty or complex incidents came under intense scrutiny. More recently, the devastation caused by Hurricane Katrina and the mass disruption of public health and medical services along the Gulf Coast spotlighted the need for cohesive strategies that focus on management systems for major public health and medical response.

As stated by the US Department of Health and Human Services (HHS), the concept of medical surge forms the cornerstone of preparedness planning efforts for major medical incidents. Medical surge refers to the ability to provide adequate medical evaluation and care during events that exceed the limits of the normal medical infrastructure of an affected community. It encompasses the ability of health care organizations to survive a hazard impact and maintain or rapidly recover operations that were compromised (a concept known as *medical system resiliency*).

HHS makes a distinction between medical surge capacity and medical surge capability. Capacity relates to the ability to handle an overall increase in volume of patients, whereas capability refers to the ability to handle patients who are presenting with problems (e.g., a highly contagious disease) that are not normally handled at the location, as well as patient populations who are not normally handled (e.g., pediatric patients at a nonpediatric facility).

During a disaster, three categories of “players” must be ready to act: public health, individual facilities, and the community at large. Therefore it is important to consider surge capacity as it relates to each of these players. Table 1 summarizes the definitions of surge capacities at each of these levels.

Surge capacity plans should be scalable and flexible to cope with the many types and varied timelines of disasters. Improving surge capacity involves a multidisciplinary approach that includes all relevant partners and functions, from each of the community’s health care facilities to local, state, and federal agencies. Facility-based or “surge in place” solutions maximize health care facility capacity for patients during a disaster. When these resources are exceeded, community-based solutions, including the establishment of off-site hospital facilities, may be implemented [1].

This article focuses primarily on approaches for hospital surge capacity planning. The section titled “Surge Patterns” discusses

Table 1. Definition

Term	Definition
Surge capacity	Ability to manage a sudden, unexpected increase in patient volume that would otherwise severely challenge or exceed the current capacity of the health care system
Surge capability	Ability to manage patients who require specialized evaluation or interventions that are not normally provided at the facility/location (e.g., contaminated, highly contagious, or burn patients)
Public health surge capacity	Ability of the public health system to increase capacity not only for patient care but also for epidemiologic investigation, risk communication, mass prophylaxis or vaccination, mass fatality management, mental health support, laboratory services, and other activities
Facility-based surge capacity	Actions taken at the health care facility level that augment services within the response structure of the health care facility; may include responses that are external to the actual structure of the facility but are proximate to it (e.g., medical care provided in tenting on the hospital grounds). These responses are under the control of the facility's incident management system and primarily depend on the facility's emergency operations plans.
Community-based surge capacity	Actions taken at a community level to supplement health care facility responses. These may provide for triage and initial treatment, nonambulatory care overflow, or isolation (e.g., off-site "hospital" facility). These responses are under the control of the jurisdictional response (e.g., public health, emergency management) and represent a public effort to support and augment the health care system.

related issues on hospital surge patterns. The section titled "Components of Surge Capacity" reviews the four component of surge capacity: care personnel and staff, facilities, equipment and supplies, and incident management system. This is followed by a discussion of balancing daily operational efficiency and maintaining appropriate surge capacity in the section titled "Balancing Daily Operational Efficiency and Maintaining Appropriate Surge Capacity." The section titled "International Collaboration" highlights the importance of international collaboration. The section "Operations Research Methodologies" provides a brief overview of OR methodologies, including simulation, optimization, stochastic processes and systems dynamics models used in medical surge analysis. The article concludes with the section "challenges."

MEDICAL SURGE

Surge Patterns

In order to better plan for hospital surge capacity during emergency events, researchers have studied data from various disaster events in the past decade to obtain a glimpse of the impact on the health care facilities from these events.

Okumura *et al.* [2] investigated the case of 640 victims of the 1995 Tokyo gas attack, focusing on their symptoms and treatment. Case studies were given to describe the symptoms of patients upon arrival and the associated treatment provided. Emergency department (ED) treatment consisted mostly of administration of atropine sulfate and dosage with 2-PAM within a few hours of the initial exposure to sarin gas for severe and moderate cases. A few clinical management

issues were raised. These included poor ventilation in the ED area, inadequate decontamination due to privacy provision and the large number of affected population, required patient followup, and monitoring for long-term health effects.

Hogan *et al.* [3] studied the pattern in epidemiologic injury data on patients who suffered acute injuries after the 1999 Oklahoma City bombing and concluded that more seriously injured patients tend to arrive in a second wave at EDs since they are less mobile and often require on-site treatment. It is understandable that the closest hospitals received the greatest number of victims by all transportation methods initially. There are lessons learnt for EDs in terms of preparing for such phenomenon and to prepare and allocate/mobilize resources accordingly. Disaster response planning should avoid overloading hospitals in the vicinity of disasters. Rapid arrival of patients with nonlife threatening injuries may overwhelm the EDs. In this case, EDs must equip themselves with clinical personnel who can perform rapid assessment and stabilization, instead of staffing with specialty doctors who generally lack such skills.

Roccaforte [4] reviewed various aspects of response by Bellevue Hospital Center to the 2001 World Trade Center attack, including challenges faced with communication, organization, staffing, and logistics. The hospital is 2.5 miles from the site of the attack. When the news just arrived, communication channels were overloaded. Poor communication hindered adequate response planning and therefore wasted resources. Fortunately, the response was well supported by full staffing on the day of the event. Obviously, full staffing would likely not be in place if an emergency event occurred at night or on a weekend or holiday. In any event, the on-hand workforce should be allocated to control and preserve important resources for likely more serious cases in the second wave. Upon arrival of patients, they were triaged based on injury conditions. Out of the 90 patients that arrived during the first 5 h, 56 had minor injuries and most of them had respiratory complaints. Five of the 90 patients suffered mixture of fractures and burns. Three patients were seriously injured.

Schull *et al.* [5] investigated the surge capacity associated with restrictions on nonurgent hospital utilization and expected admissions during the Toronto Severe Acute Respiratory Syndrome (SARS) outbreak. The study compared expected influenza-related hospitalization with the actual reduction in hospital admission for eight weeks for three different pandemic severity levels: mild, moderate, and severe. It was found that influenza-related admissions generally exceed the reduction in admissions of nonurgent cases. Thus, simply reducing hospital admissions may not be sufficient for handling an influenza-related medical surge. Other strategies should be explored.

Gavagan *et al.* [6] examined medical response in the aftermath of Hurricane Katrina at the Houston Astrodome/Reliant Center Complex. During the two weeks of operation, the center provided shelter to 27,000 evacuees, over 11,000 of whom sought some form of medical care. Common health problems with the patients included uncontrolled hypertension, respiratory infection, and acute gastroenteritis. At the medical center, five levels of care characterized treatment, from immediate triage upon arrival to the use of community resources. Most of the adult visits to the Katrina clinic were related to chronic disease or medication refills. Another major health condition found in adults related to skin problems as a result of exposure to tainted water. Over 3500 children and infants were seen at the medical center during a two-week span. People 65 or older accounted for 56% of the total patients seen, and 62% of the 37 total deaths. Other problems that were addressed include mental health as well as obstetrics and gynecology. In terms of personnel management, instances were found where noncredentialed people setup medical clinics within the center, raising the critical issue of careful verification of staff qualification.

Stratton and Tyler [7] studied characteristics of medical surge capacity demand data based on existing databases and literature and concluded that the earliest outside assistance for a community subject to a sudden-impact disaster arrived in roughly 24 h, with a range that reached to 96 h. After

sudden-impact disasters, 84–96% of health care demand was managed by ambulatory care. EDs were the access point for care, with peak demand time occurring within 24 h. The authors also suggested that lack of standards for reporting disaster data and limited depth of the current disaster literature are limitations for surge capacity related research.

Components of Surge Capacity

Surge capacity encompasses multidimensional aspects such as potential patient beds; available space in which patients may be triaged, managed, vaccinated, decontaminated, or simply located; available care personnel of all types; necessary medications, supplies, and equipment; and even the legal capacity to deliver health care under situations that exceed authorized capacity. Further, close collaboration between public health and health care facilities is very important to effective disaster response.

Surge capacity is tight in the nation's hospitals, as hospitals have undergone years of budget tightening and consequent efforts to control costs, resulting in diminished patient capacity. Another factor that affects rapid response to surges includes an overall shortage of nurses. In a 2006 nationwide blue-ribbon panel of health care experts, led by Dr. Kelen, head of emergency medicine at The Johns Hopkins Hospital and Director of the Johns Hopkins Office of Critical Event Preparedness and Response, it was recommended that hospital plans for a surge of disaster victims should begin with a strategy to empty their beds of relatively healthy patients. Preliminary data suggest that such a strategy could safely empty 70% of a hospital's inpatient population within 72 h.

There is consensus among health care officials that, whether dealing with a natural disaster like Hurricane Katrina, a possible terrorist attack like September 11, or epidemics like SARS or avian flu, affected hospitals have few means of making room for large numbers of incoming casualties.

In one common disaster response, medical centers would setup additional beds wherever they can (in hallways, cafeterias, etc.). But, there is serious concern that staffing

levels could not expand to care for so many new patients, and "disposition classification" is being recommended as a must. Such an approach is important as it ensures that both the disaster victims as well as those patients who are already hospitalized, all would receive adequate treatment.

Disposition classification puts patients in one of five categories, based on their considered risk of a life-threatening or life-impairing medical problem within 72 h of hospital discharge. Patients classified as "minimum" risk could go home upon being discharged. Those in the "low-risk" group could also be transferred home depending on the severity and scope of the disaster. Those in the "moderate" category could not go home but could be transferred to a facility offering basic medical resources. "High-risk" patients could only be transferred to an acute-care facility and "very high-risk" patients could only be served in a critical care facility.

The decision making process is complex and the logistics behind transferring such a large number of patients to other facilities is hardly trivial. However, it offers an ethical and nonemotional approach, and could be implemented outside of a disaster situation as a tool to manage even routine, everyday overloads of hospital resources [8].

The four critical areas comprising hospital surge capacity identified by various investigators are personnel, facility, equipment and supply, and management [9]. Generally, hospitals have a concept on the amount of resources required for each category above a given number of patients. Therefore, improving surge capacity centers around the problem of determining how much a hospital could expand their capacity, how quickly the expansion can be implemented, and how long it can be sustained. For example, an arbitrary amount of 20% on top of normal capacity has been set for Israeli hospitals. In the United States, the Health Resource and Service Administration provides a surge guideline of 500 beds per one million population for patients with symptoms of acute infectious disease and 50 beds per one million population for noninfectious disease and injury [10]. It is also noted that a hospital will be unable to further increase surge

capacity once its saturation point has been reached. Strategies for determining when hospitals will reach this position currently do not exist [9].

We will now discuss each of these four areas in more detail.

Care Personnel and Staff. When disaster happens, it is natural for hospitals to increase the number of staff by maximizing the use of their own personnel. This requires established protocol for revision of staff work hours (e.g., a 12-h shift is standard in disaster events), call-back of off-duty personnel, use of nonclinical staff (e.g., nurse administration) in clinical roles as appropriate, and reallocation of outpatient staff resources [1].

One possibility to further support hospital staffing requirements is by providing emergency credentialing to volunteer health care professionals. However, many issues relating to this practice need to be addressed: for example, an institution's willingness to permit such individuals to work in their facility, credibility and confidentiality issues, and retention of such workers if they are needed for a time period that goes beyond expectation. Schultz and Stratton [11] suggested a solution to credential issues by sharing a database of credentialed health care workers among mutually acceptable organizations which will then assist in staff planning during disasters. In addition, family members could also assist in taking care of patients.

As discussed, the least serious casualties usually arrive at the hospital first during a disaster. Health care personnel may not be aware that more serious patients are yet to arrive. Careful planning must take this factor into consideration to avoid filling existing beds with minor injuries [12]. The "disposition classification" scheme can be used to help with proper resource allocation [8].

Research was conducted on health care workers' ability and willingness to report to duty during catastrophic disasters [13]. It was reported that one-fourth to one-third of the workforce may be deliberately absent for some period when the use of weapons of mass exposure was involved. Therefore, staffing during disaster will be a serious problem. In our own work, we focus on

optimal (minimizing) resource allocation and staffing assignment for mass population protection, and improving system throughput via maximizing operations efficiency, optimal clinic layout design, and process workflow [14–17] (see **Public Health, Emergency Response, and Medical Preparedness II: Medical Countermeasures Dispensing and Large-Scale Disaster Relief Efforts**).

Facility. Expanding bed capacity during an emergency can be accomplished by multiple strategies. These include the following:

- *Reduce Current Bed Occupancy:* such as canceling elective procedures, early discharge of inpatients [18], and clearing patients with minor injuries;
- *Expand Capacity Within Hospital:* including converting single rooms to double occupancy, using flat space as patient care wards, and using alternative sites in the parking lot;
- *Collaboration with Other Hospitals and Community Facilities:* including transferring patients to nearby hospitals or health care facilities and collaborating with other community organizations such as schools and churches for patient treatment and storage of supplies.

Some of the issues associated with facility expansion include the following:

- *Nature of Disaster and Effected Areas.* For example, in times of natural disasters such as hurricanes or earthquakes, large areas may be affected at the same time, thus making the transfer between hospitals or nearby community centers impossible;
- *Security Issues with Temporary Health Care Facilities.* For example, setting up temporary hospitals in tents is a common practice after earthquake events. These facilities are often open to the public, thus making it difficult to control access and prevent theft of equipment and supplies;

- *Local Practicality.* The practicality of the site is influenced by the climate and infrastructure support (e.g., water, electricity, and other utilities).

Equipment and Supplies. Building surge capacity must also take into consideration the requirement on equipment, supplies and pharmaceuticals on top of availability of wards, space, and medical staff. In the United States, the Strategic National Stockpile (SNS) is a program developed by the federal Centers for Disease Control and Prevention (CDC) Bioterrorism Preparedness and Response Initiative that assists states and communities in responding to extreme public health emergencies from terrorist attacks or natural disasters. SNS has large quantities of medicine and medical supplies to protect the public in a health emergency. The SNS is operated as a collaborative effort between local, state, and federal officials. The SNS contains medicines, vaccines, medical and surgical supplies, life-support medications, and breathing supplies. It is not a first response tool. Rather, it is designed to supplement and resupply a local and/or state response to an emergency within the United States or its territories. The two major components of the stockpile are 12-h Push Packages and the Managed Inventory. The Push Packages contain 50 tons of pharmaceuticals, antidotes, and medical supplies that will treat a variety of illnesses. Managed inventory can either replenish the Push Package or be tailored with specific medical supplies to respond to a defined agent or other specific public health threat. The 12-h Push Packages arrive within 12 h once deployed at the federal level. Supplies are distributed to local communities as quickly as possible. Managed inventory is shipped to arrive within 24–36 h after deployment (see ***Public Health, Emergency Response, and Medical Preparedness II: Medical Countermeasures Dispensing and Large-Scale Disaster Relief Efforts***).

Major issues with medical supplies and equipment held are as follows:

- *Speed of Delivery.* Hanfling [19] argued that it is necessary for each local

community to create a local cache for these items. He further explored the funding requirements for this approach.

- *Amount of Supplies to Stockpile.* It is possible that stockpiled supplies that are very expensive are no longer functional when a disaster outbreak happens (e.g., ventilators used for pandemic influenza). Whether we should stockpile for worst-case scenario or most likely scenario is another issue to be discussed.
- *Strategies for Effective Dispensing.* For example, in the event of an infectious disease outbreak or a biological attack, operational and strategic plans must be designed and put in place to dispense the medical supplies (e.g., vaccines, antibiotics) to the affected population effectively and efficiently [14–17] (see ***Public Health, Emergency Response, and Medical Preparedness II: Medical Countermeasures Dispensing and Large-Scale Disaster Relief Efforts***).

Incident Management System. Incident management systems and cooperative planning processes will facilitate maximal use of available resources. However, resource limitations may require implementation of triage strategies.

In building surge capacity, Burkle [20] investigated a population-based bioevent triage management with the goal of identifying the population requiring immediate care, preventing secondary transmission and building surge capacities that are population specific. In this management method, the population self-identify into one of five categories: susceptible but not exposed, exposed but not yet infectious, infectious, removed by death or recovery, and vaccination or prophylactic medication.

One of the most important issues of surge capacity is the ability to implement an incident management system. In the United States, one of the most conflicted issues with incident management is that the health care system includes many private entities. Private hospitals have no jurisdictional boundaries and are not under

any governmental or municipal operational authority or control. Successful implementation of an incident management system for effective disaster response requires careful planning and close collaboration between public health and (private) health care facilities, and organizations from the local level to the federal government level.

Balancing Daily Operational Efficiency and Maintaining Appropriate Surge Capacity

With the need to balance budgets, hospital administrators often look toward closures and downsizing to reduce costs, and toward process optimization to improve efficiency. These efforts to decrease costs and increase efficiency often run counter to simultaneous efforts to enhancing or maintaining surge capacity, as staffing and usage of resources are maintained at very high utilization rates, leaving very little room for medical surge. There is also a serious gap between daily surge capacity versus rapid large-scale surge requirements for catastrophic events.

Among the many issues that the US Congress needs to address for public health and medical preparedness and response, medical surge capacity has been identified as inadequate. The Government Accountability Office (GAO) issued an updated report in January 2010, “State Efforts to Plan for Medical Surge Could Benefit from Shared Guidance for Allocating Scarce Medical Resources.” The report states that many hospitals in the United States are unprepared for treating the overwhelming “surge” of victims from a large-scale mass casualty event. GAO said that “based on a review of state emergency preparedness documents and interviews with 20 state emergency preparedness officials, many states had made efforts related to three of the four key components of medical surge that GAO had identified—increasing hospital capacity, identifying alternate care sites, and registering medical volunteers, but fewer had implemented the fourth: planning for altering established standards of care. More than half of the 50 states had met or were close to meeting the criteria for the five medical surge-related sentinel indicators for hospital capacity reported in

the Hospital Preparedness Program’s 2006 midyear progress reports. In a 20-state review, GAO found the following. All 20 were developing bed reporting systems and most were coordinating with military and veterans hospitals to expand hospital capacity. Eighteen were selecting various facilities for alternate care sites. Fifteen had begun electronic registering of medical volunteers, and fewer of the states—7 of the 20—were planning for altered standards of medical care to be used in response to a mass casualty event.”

International Collaboration

As illustrated vividly by the recent tsunamis and the 2010 Haiti earthquake, surge capacity remains critical when catastrophic events elsewhere in the world demand it. Research has been done internationally on improving health care surge capacity in the face of a high-consequence event. Peleg and Kellermann [21] summarized 14 principles developed by Israel’s Ministry of Health on enhancing system surge capacity. Shih and Koenig [22] also discussed Taiwan’s experience in managing surge needs through sending doctors to the scene of an event, immediately recalling off-duty hospital personnel, managing volunteers, designating specialty hospitals, and use of incident management systems.

In the recent Haiti situation, the destruction of the local health care infrastructure required reaching out to hospitals outside the country, as well as immediate establishment of a network of on-site health-care facilities. In this case, the United States naval ship USS Comfort served as an acute treatment site, whereas temporary make-shift hospital tents were setup to provide medical care for the mass injured. This illustrates the intimate and critical interplay between hospital surge capacity and the urgent need for setting up (temporary) facility-based and community-based solutions to manage medical surges.

OPERATIONS RESEARCH METHODOLOGIES

Among operations research methodologies, simulation, optimization, stochastic

processes, and system dynamics models are often employed in the field of medical surge analysis.

A system dynamics model was developed by Manley *et al.* to assess hospitals ability to handle surges of demand during disasters [23]. The model represents all major flows of patients through the hospitals and helps the hospital to identify potential bottlenecks in the system when facing various situations.

Thompson *et al.* [24] attempted to solve the optimal reallocation problem for proactively transferring patients between floors in anticipation of demand surge by modeling it as a finite-horizon Markov decision process. A decision-support system based on the optimization model was implemented at Windham Hospital in Willimantic, Connecticut. It was estimated that this implementation projects a financial gain of 1% of the hospitals total revenue and a 50% reduction on the average wait time for an admitted patient to be transferred to a floor.

Gerchak *et al.* [25] developed a stochastic dynamic programming model for scheduling of elective surgery when the operating rooms capacity utilization is uncertain. The model addresses the trade-off between timeliness of admission and reserving capacity for emergency cases.

Einav *et al.* [26] suggested guidelines for hospital resource utilization during terror-related multiple casualty incidents based on data gathered from six level I trauma centers. It was found that there is a high demand for ED, OR, and ICU. Anesthesiologists, general, thoracic, and vascular surgeons are in immediate demand. ICU admissions occur simultaneously with ongoing patient arrival to the ED. Most patients operated on within the first 2 h require multidisciplinary surgical teams. Demand for orthopedic and plastic surgery and anesthesiology services continues for more than 24 h.

Patrick and Puterman [27] demonstrated how queueing theory provides managers with insights into the causes for excessive wait times and the relationship between wait times and capacity. A case study involving Markov decision process, linear programming, and simulation was included to optimize the scheduling of patients with

multiple priorities. It was shown that a wait time target can be achieved with judicious use of surge capacity in the form of overtime when applying the above methods.

Paul *et al.* [28] attempted to accurately model the behavior of the system by a transient modeling approach using simulation and exponential models. The parameters of the exponential model were regressed using outputs from designed simulation experiments. The model allows real-time estimation of capacity for hospitals of various sizes. Priority-based routing of patients within the hospital is also allowed in the modeling, where patients are guided based on the severity of injuries.

Roccaforte and Cushman [29] researched resource organization for optimally matching the demand and capacity of the treating facility.

Hoard *et al.* [30] introduced a conceptual framework for a study that applies a system dynamics approach to rural disaster preparedness and planning. This approach can be used for building computer simulation models and applies to hospital surge capacity to answer various “what-if” questions such as placing supplementary nursing staff for emergency outbreaks.

Green [31] addressed some problems faced in hospital capacity planning, such as government impact, competition, and influence of managed care. Oftentimes, the decision maker makes these complex decisions based on routine or experience. Green provided examples of how OR models can be used to provide insights into operational strategies and practices.

In our own work, the decision-support system RealOpt combines OR modeling techniques, novel and large-scale computational engines, sophisticated graph-drawing tools, 3D geographical spatial information with federal census data, and demographic and socio-economic data for operational and strategic planning, and policy analysis (see **Public Health, Emergency Response, and Medical Preparedness II: Medical Countermeasures Dispensing and Large-Scale Disaster Relief Efforts**). Within the medical surge area, RealOpt allows public health emergency coordinators to (re)design

customized, efficient floor plans for each facility via an automatic graph-drawing tool; identify effective triage strategies, and determine (in real-time) optimal resource allocation through advanced computational techniques in simulation and optimization [14–17]. This allows hospital managers the ability to perform scenario-based analysis and determine the best course of action in response to the medical surge requirement.

CHALLENGES

Large-scale public health emergencies may involve thousands of sick or injured people who will require various levels of medical care, ranging from patient evacuation (see **Public Health, Emergency Response, and Medical Preparedness IV: Emergency Evacuation**), hospital care, and sustainable and potentially long-term health-recovery procedures. Thus, such emergencies present a daunting set of challenges, including the surge capacity and capability, and flexibility of our existing medical systems, federal and state emergency capacity for rapid medical dispensing for population protection (see **Public Health, Emergency Response, and Medical Preparedness II: Medical Countermeasures Dispensing and Large-Scale Disaster Relief Efforts**), and the resolve and resilience of health-care workers and emergency responders to perform under critical timelines and exceedingly stressful conditions.

Surge capacity encompasses multidimensional aspects such as potential patient beds; available space in which patients may be triaged, managed, vaccinated, decontaminated, or simply located; available care personnel of all types; necessary medications, supplies, and equipment; and even the legal capacity to deliver health care under situations that exceed authorized capacity. Further, close collaboration between public health and health care facilities are very important to effective disaster response. The 2006 Academic Emergency Medicine Consensus Conference discussed the key concepts within the field of surge capacity. Specifically, five top topics were listed as research priorities [32]:

- defining criteria and methods for decision making regarding allocation of scarce resources;
- determining effective triage protocols,
- determining key decision makers for surge-capacity planning and means to evaluate response efficacy (e.g., incident command);
- developing effective communication and information-sharing strategies (situational awareness) for public-health decision support, and
- developing methods and evaluations for meeting workforce needs.

Modeling and optimizing public health infrastructure involve elements of resource allocation under risk, uncertainty, and time pressure; large-scale supply-chain management; transportation and operational logistics; and medical treatment (*medical surge*), population protection (see **Public Health, Emergency Response, and Medical Preparedness II: Medical Countermeasures Dispensing and Large-Scale Disaster Relief Efforts**), and effective evacuation (see **Public Health, Emergency Response, and Medical Preparedness IV: Emergency Evacuation**). The operations must be supported by an effective communication infrastructure (see **Public Health, Emergency Response, and Medical Preparedness III: Communication Infrastructure**). There is a necessity for vertical and horizontal integration and communication, where federal, state, local, tribal, territorial, private and business stakeholders work toward a common goal of a resilient public health system. The infrastructure must be *flexible, scalable, sustainable, and elastic* to support an effective and timely response, and to mount rapid recovery and mitigation operations.

Acknowledgment

Part of the material and results reported herein are based on our work in this area and interaction with public health agencies, and discussion with many state and federal public health and emergency response experts. We also acknowledge the funding from the CDC.

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

INTRODUCTION

A catastrophic health event, such as a terrorist attack with a biological agent, a naturally occurring pandemic, or a calamitous meteorological or geological event, could cause tens or hundreds of thousands of casualties or more, weaken the economy, damage public morale and confidence, create panic and civil unrest, and threaten national security. It is therefore critical to establish a strategic vision that will enable a level of public health and medical

preparedness sufficient to address a range of possible disasters. Although present public health and medical preparedness plans incorporate the concept of “surging” existing medical and public health capabilities in response to an event that threatens a large number of lives, the assumption that conventional public health and medical systems can function effectively in catastrophic health events has proven to be incorrect in real-world situations. Therefore, it is necessary to transform the approach to health care in the context of a catastrophic health event in order to enable public health and medical systems to respond effectively to a broad range of incidents.

According to the US Department of Homeland Security Presidential Directive 21 2007, public health and medical preparedness refers to “the existence of plans, procedures, policies, training, and equipment necessary to maximize the ability to prevent, respond to, and recover from major events, including efforts that result in the capability to render an appropriate public health and medical response that will mitigate the effects of illness and injury, limit morbidity and mortality to the maximum extent possible, and sustain societal, economic, and political infrastructure.”

Planning for a catastrophe involving a disease outbreak or mass casualties is an ongoing challenge for first responders and emergency managers. They must make critical decisions on treatment distribution points, staffing levels, impacted populations, and potential impact in a compressed window of time when seconds could mean life or death. Although extensive resources have been devoted to planning for a worse-case scenario on the local, regional and national scale, the US Government Accountability Office (GAO) found that gaps still exist. While many states have made progress in planning for mass casualty events, many noted continued concerns related to maintaining adequate staffing levels and accessing other resources necessary for an effective response.

This article highlights our own experience on projects with the Centers for Disease Control and Prevention (CDC) and various public health jurisdictions in emergency response and medical preparedness for mass dispensing for disease prevention and treatment, and large-scale disaster relief efforts. Specifically, the section titled “Population Protection: Medical Countermeasures Dispensing and Large-scale Disaster Relief Efforts” provides a brief introduction and motivation for medical countermeasure dispensing. The section titled “A Systems View of Mass Dispensing Operations: Integrating All the Elements” offers a systems view of mass dispensing operations.

In the section titled “Mode of Dispensing and POD Placement”, we describe various modes of dispensing and POD (point of dispensing) placement. This is followed by resource allocation and POD layout design in the next section. The section titled “Disease Propagation Analysis: Mitigation Strategies and Choice of Dispensing Modalities” highlights the importance of disease propagation analysis and design of mitigation strategies, while the section titled “Supply Chain Management: Demand, Supply, Fulfillment, and Partnership” describes supply chain management. In particular, we briefly explain the mission and responsibility of CDC’s Strategic National Stockpile (SNS). This is followed by the section titled “Communication and Public Information.” This entails the communication infrastructure (hardware tools and software programs) that supports emergency operations, as well as public information and risk communication. The section titled “Lessons Learnt and Continued Challenges” offers insights on lessons learned from flu mass vaccination and anthrax drill exercises, and shares our knowledge on continued challenges and the need for multilayer protection.

The section titled “Large-scale Disaster Relief Efforts” summarizes large-scale disaster relief efforts, including the establishment of a network of service constructs for food, medical needs, and shelters; staffing and resource constraints; susceptibility of displaced population to infectious

disease outbreaks; and supply chain management. Coordination among different stakeholders; risk and uncertainty that are faced by on-the-ground rescue and relief workers; and media exposure are also discussed.

In the section titled “Summary,” we summarize some methodologies that are commonly employed in emergency responses. These techniques include optimization, stochastic processes, information technology, and an integrated framework of decision systems. The article concludes with some challenges for future research.

POPULATION PROTECTION: MEDICAL COUNTERMEASURES DISPENSING AND LARGE-SCALE DISASTER RELIEF EFFORTS

Public-health emergencies such as bioterrorist attacks or pandemics demand fast, efficient, large-scale dispensing of critical medical countermeasures (i.e., vaccines, drugs, and therapeutics). Such dispensing is complex and requires careful planning and coordination from multiple federal, state, and local agencies, and the potential involvement of the private sector. Dispensing medications quickly (within 48 h for anthrax prophylactic) to large population centers (with tens of thousands or even millions of people) is urgent; moreover, the multifaceted nature of dispensing (e.g., sending federal stockpiles to local PODs, coordination at the local level to manage the transportation of citizens to PODs, and the POD operations) makes the process highly unpredictable. Thus, emergency managers and public health administrators must be able to quickly investigate alternative response strategies as an emergency unfolds.

The focus of this article is on *mass dispensing* of medical countermeasures for protection of the general population. Other issues pertinent to large-scale disaster relief efforts will also be highlighted. Much of the writing below are excerpts from our recent work with the Centers for Disease Control and Prevention on modeling and optimizing public health emergency response infrastructure and the development of a

large-scale simulation-optimization decision support system, RealOpt [1–6].

Large-scale public health emergencies may involve thousands of sick or injured people who will require various levels of medical care, ranging from patient evacuation (see ***Public Health, Emergency Response, and Medical Preparedness IV: Emergency Evacuation***), hospital care, and sustainable and potentially long-term health-recovery procedures. Thus, such emergencies present a daunting set of challenges, including the surge capacity and flexibility of our existing medical systems (see ***Public Health, Emergency Response, and Medical Preparedness I: Medical Surge***), federal and state emergency capacity for rapid medical dispatching, and the resolve and resilience of health-care workers and emergency responders to perform under critical time lines and exceedingly stressful conditions.

In the wake of the 2001 anthrax attacks, the Department of Health and Human Services (HHS) increased its order for smallpox vaccine, accelerated production, and began working to develop a detailed plan for the public health response to an outbreak of smallpox. By January 2003, the United States had sufficient quantities of the vaccine for every person in the country in an emergency situation [7]. Subsequently, HHS required each state to submit a mass vaccination plan for administering the smallpox vaccine. Further, states are charged with developing city-readiness programs that deal with establishing regional treatment and dispensing centers, and developing procedures, policies, and a planning framework for efficient allocation of staff and resources in response to these events.

The importance of such population protection has been carefully studied for human, social, and economic benefits. Kaplan *et al.* [8] argued that immediate mass vaccination after a smallpox bioterrorist attack would result in fewer deaths and faster eradication of the potential epidemic; Wein *et al.* [9] concluded that immediate and aggressive dispersion of oral antibiotics and the full use of available resources (local nonemergency care workers, federal and military resources,

and nationwide medical volunteers) are extremely important.

A SYSTEMS VIEW OF MASS DISPENSING OPERATIONS: INTEGRATING ALL THE ELEMENTS

Public health and medical preparedness involves three phases: (i) preparedness and prevention, (ii) detection and response, and (iii) recovery and mitigation.

Modeling and optimizing public health infrastructure involve elements of resource allocation under risk, uncertainty, and time pressure; large-scale supply chain management; transportation and operational logistics; and medical treatment and population protection. The operations must be supported by an effective communication infrastructure (see ***Public Health, Emergency Response, and Medical Preparedness III: Communication Infrastructure***). There is a necessity for vertical and horizontal integration and communication, where federal, state, local, tribal, territorial, private, and business stakeholders work toward a common goal of a resilient public health system. The infrastructure must be *flexible, scalable, sustainable, and elastic* to support an effective and timely response, and to mount rapid recovery and mitigation operations [5,6,10].

The global integration plan for population protection in the event of medical and emergency response includes multiple interconnected components: strategic planning; management command and control with key leaders working cohesively together as a team; requesting supplies and equipment from Strategic National Stockpile (SNS) tactical communication and information technology; public information and risk communication; security; regional and local distribution sites (for receiving, staging, and storing of supplies, as well as transportation and routing); inventory control and management; distribution supply and resupply; dispensing; treatment centers; and planning, training, and evaluation [10]. The ultimate goal is to *dispense* the medical countermeasures to the affected regional population in a timely manner.

Mode of Dispensing and POD Placement

Mass dispensing requires the rapid establishment of a network of dispensing sites and health facilities that are *flexible*, *scalable*, and *sustainable* for medical prophylaxis and treatment of the general population. Moreover, each POD must be capable of serving the affected local population within a specified short time frame (Fig. 1). Clearly, for very large-scale dispensing, the sophisticated logistical expertise needed to deal with the complexities of selecting an adequate number of strategically well-placed POD locations, and of designing and staffing each POD, is beyond the capability of any human planner or public health administrator. The limited availability of trained critical staff, such as public health professionals, further compounds the inherent complexities.

The CDC and public health administrators work closely with one another to prepare for and document the steps required to administer medication in the event that mass dispensing is needed. The goal and objectives of a dispensing facility, *POD*, are to deliver appropriate emergency services (e.g., vaccine, medical service, and education/training) to high-risk populations in an orderly, expeditious, and safe manner. Within the POD facility, the potential tasks and objectives may include the following:

1. Assess health status of clients.
2. Assess eligibility of clients to receive service.
3. Assess implications of each case and refer case for further investigation if necessary.
4. Counsel clients regarding service and associated risks.
5. Administer service.
6. Educate regarding adverse events.
7. Document services.
8. Monitor vaccine take rates.
9. Monitor adverse reactions.
10. Monitor development of disease.

Mode of Dispensing. The *key* to mass dispensing is to protect the general population efficiently and effectively under time pressure. For example, in an anthrax attack, the goal is for citizens to receive antibiotic prophylaxis within 48 h of the determination that an attack has occurred, as the mortality rate for persons demonstrating symptoms of inhalation anthrax is extremely high. (Lawler JV, Mecher CE. Homeland Security Council. 2007. Private Communication.) Thus, it is recognized that multiple dispensing modalities often must be employed in order to *serve (cover)* the entire regional population. For example, special dispensing services will be utilized to serve homebound, disabled, and special-need populations. In

Figure 1. The flowchart shows a POD that was set up in a national drill exercise to dispense anthrax antibiotics.

some instances, it is unreasonable to expect residents to travel to a designated POD facility. For example, nursing homes, assisted living facilities, homeless shelters, hospitals, and prisons house many residents for whom it would be inconvenient or inadvisable to travel to a public dispensing facility. Moreover, in many of these instances, there are already medical personnel on site who can assist in the dispensing process. In such cases, it would be more efficient to set up a *closed* POD inside these locations for dispensing, or to have medication dispensed by a mobile POD facility near the site. In this case, the POD is *closed* as it provides services only to the residents on-site, and is not open to walk-ins from the general public. Corporate offices that staff a large number of employees could be served in a similar manner. Once these sites receive prophylactic supplies, they could set up a closed POD within their building, with their own health-care staff and volunteers, or with public health staff supplemented by the state. Several factors suggest that such closed PODs will have fewer security concerns and will be easier to manage than public PODs. These factors include familiarity with the environment and people (e.g., fellow residents/employees), existing security measures including established checkpoints and previously authenticated identification badges with photo and/or biometric markers, and less stress than having to commute to a public POD.

Airports and hotels, where a large number of nonresident travelers can be found, are also candidates for setting up PODs to service specific vulnerable populations. Universities can use their own health facilities (and if necessary, additional mobile on-campus PODs provided by the state) to provide prophylaxis to on-campus students, staff, and faculty. Clearly, if large employers and medical facilities provide prophylaxis to their own employees, families, and patients, it will eliminate a high percentage of the population (may be as high as 40% in some large cities) from visiting public PODs, thus reducing the load on those facilities.

Public PODs are *open* facilities that are setup to serve the general public.

In our work with CDC [2,3,5,6], public PODs have generally been described as being setup inside existing facilities, or in outdoor tents, with areas set aside for various activities in the dispensing process, including assembly/intake, triage, orientation, registration, screening, service, education, and discharge. Public PODs can be mobile or stationary, and in the latter case, they can be setup as *facility-based* or *drive-through*.

A facility-based POD operates within physical locations, such as buildings, warehouses, open fields, or large parking lots. Citizens are asked to arrive at the POD location and then *walk through* the POD to receive their medication or other treatment. Facility-based PODs may be scaled to operate within a setting as large as a professional sports stadium or as small as a volunteer fire house within a rural community.

These walk-through PODs are suitable for relatively large capacity facilities, where the possibility of traffic jams preclude the use of the drive-throughs. Because parking is typically limited, individuals may be directed to arrive at designated points, and they are taken by bus to the POD. Examples of pickup points include bus stations, subway stations, and parking lots of large shopping malls, where sufficient parking is available.

High schools are often selected as potential POD locations. The fact that they are government-owned makes logistics easier. Other considerations include existence of offices, computer communications, cafeterias, and storage. Shopping malls, churches, and stadiums are also suitable and in some cases, PODs are set up outdoors using tents and temporary constructs.

Drive-through PODs are suitable to serve a spread-out population. Ideally, government-owned properties are preferred over privately owned ones for logistic reasons. Locations for setting up drive-through facilities should have enough space for multiple dispensing lanes; surrounding access roads; and room for command tent, employee rest area, and medication storage.

POD (Facility) Placement. Facility location problems are classical optimization problems, and have been a critical element in

strategic planning for a wide range of private and public organizations. The earliest facility location problems incorporating emergency response relate to location of emergency facilities [11–13]. Chaiken and Larson [14] provided a survey on urban emergency unit allocation. Some researchers [15–17] explicitly take the need for backup facilities (in case the main facility is overloaded) into account. More recently, Jia *et al.* [18] provided a modeling framework for location of medical services for large-scale emergencies. Berman and Gavious [19] took a game theoretic approach toward location of terror response facilities. Church *et al.* [20,21] studied the problem of identifying and protecting critical infrastructure. A comprehensive review of facility location research can be found in Brandeau and Chiu [22], where the authors presented a survey of over 50 representative problems in location research. Most of the problems reviewed have been formulated as optimization problems. Owen and Daskin [23] provided another review of the strategic facility location problem; they considered a wide range of model formulations across numerous industries, including stochastic formulations, and discussed solution approaches.

While many of the facility location problems involve permanent construction and establishment of service facilities, facility location problem for mass dispensing concerns the placement of PODs (mobile or stationary) in existing facilities (e.g., high schools, stadiums, shopping malls, open parking lots) in a region to provide the necessary services to the population within a designated period of time.

Various objectives can be incorporated within the models. In the event of catastrophic incidents, it is critical that PODs are strategically located so as to allow easy access by the affected public. Hence, minimizing transportation time can be one critical objective. Further, the setup and operating costs of PODs cannot be neglected. A POD must be accessible by service workers, it should include a good communication infrastructure, it must be easily protected by law-enforcement personnel, and the facility must be capable of handling a large flow of

people. Physical constraints on the facility must be modeled properly, for example, capacity of a facility cannot be violated (POD parking capacity is limited and fire codes limit the number of individuals who can be inside a facility simultaneously).

For operational purposes, there is also a desire to ensure that the number of PODs in each jurisdiction is at least two. This is due to the concern that if a catastrophic event at one site necessitates shutting down of a POD, emergency dispensing can still be carried out in the remaining location. In this case, the response manager can reroute populations to the remaining site, while reestablishing a new POD, if deemed necessary.

The problem of modeling POD placement involves the traditional facility location issues, as well as the incorporation of spatial, geographical, and demographic information. In our work with CDC, the problem is modeled using a two-stage integer programming approach. For a large metropolitan area with a population over 5 million, such a POD placement problem can result in optimization (integer programming) instances involving millions of variables and constraints for each jurisdiction that consists of hundreds of thousands of people in the region. The challenge is to determine the trade-offs between the quality of solution, the practicality of planning, and real-time optimization. Exact algorithms and heuristics must be developed and advanced to address such computational challenges [5,6].

Resource Allocation and POD Layout Design

Resource Allocation. Mason and Washington [24] at CDC investigated optimal staffing arrangements for dispensing sites in the face of limited resources via a simulation/optimization system “Maxi-Vac” that they developed. Their study offered insights on the practicality of such a system as a planning tool for emergency situations but revealed critical bottlenecks between the commercial simulation software and the optimization software: over 10 h were needed to obtain a usable feasible solution in each scenario with about 25–30 staff. This initiated our collaboration with CDC and the development of RealOpt, a large-scale

real-time simulation-optimization decision support system [1–3].

Given a staff assignment (obtained from an initial optimization step), and input of service distributions at each station, we can model and simulate the movement of individuals inside a POD. The simulation output is a set of parameters (including statistics of average flow time, queue length, wait time, and utilization rate) that enable evaluation of the objective function being optimized (e.g., the resulting throughput).

The optimization of labor resources involves placement of staff at various stations in the POD to maximize throughput or minimize the staffing needs to satisfy a preset throughput population. The cost at each station depends on the type and number of workers who are assigned to that station and have the required skills, and on the average wait time, queue length, and utilization rate of the station. The total system cost depends on the cost at each station and on system parameters, such as cycle time and throughput. These cost functions are not necessarily expressible in closed form.

Constraints in the model include maximum limits on average wait time and queue length, range of utilization desired at each station, and upper and lower bounds on the number of workers with the required skills who are needed to perform various tasks at the POD. Constraining the average cycle time to be less than a prespecified upper bound is critical for emergency response, because individuals must move through the system as quickly as possible to facilitate crowd control, reduce sources of human frustration and potential disorderly outbursts, and reduce the potential spread of disease or contamination. The resulting nonlinear mixed-integer program poses unique challenges for existing optimization engines.

POD Layout Design. Designing the appropriate POD for various medical dispensing is critical. Further, POD layout will affect the overall staffing and efficiency of the dispensing operations.

Figure 2 contrasts two POD designs that were employed in a hepatitis A booster shot

event for 10,000 citizens [25]. The left shows the drive-through POD design used in the morning, and the right shows the redesign in the afternoon after real-time reconfiguration (based on service times collected on site) was performed. The redesign offers 10% improved throughput, 18% improved utilization, and a range of 10–85% reduction in wait time and queue length at various stations. *This illustrates the paramount importance of POD design to any emergency operation where resources are scarce, time is precious, and there is a large affected population to serve.*

Disease Propagation Analysis: Mitigation Strategies and Choice of Dispensing Modalities

Large-scale dispensing clinics could facilitate the spread of disease because of their high-volume population flow. The field of dynamical systems (mostly differential equation systems) provides the principle methods of modeling in classical mathematical epidemiology [26,27]. Despite their simplicity when compared to recent complex simulation studies [28–31], these methods have helped generate functional insights, such as the transmission threshold for the start of an epidemic and the vaccination threshold for containment of an outbreak. As modelers attempt to incorporate more realistic dynamics into their models (such as stochasticity, nonexponential waiting times, sample-path dependent events, and demographical and geographical data), more flexible tools such as individual-based stochastic simulations are preferable. Although simulation is a powerful approach, it is less mathematically tractable (i.e., it requires intensive computing time) than the classical methods.

The rapid and large-scale simulator in RealOpt opens up an opportunity to explore disease propagation studies in which stochasticity of systems can be incorporated readily. It includes a disease propagation module that aids users in understanding facility design and flow strategies that mitigate the spread of disease. The module incorporates the standard four-stage SEIR (susceptible, exposed, infectious, and recovered) model [32], and a novel six-stage SEPAIR model to capture the disease development (i.e., asymptomatic or

Figure 2. Two POD layouts used during an actual 2008 hepatitis vaccination event.

symptomatic). By distinguishing the symptomatic stage from the asymptomatic stage, this model allows one to examine the effect of triage accuracy in POD facility design.

Lee *et al.* [6,33] gave a detailed theoretical and computational analysis of disease propagation and strategies for mitigation during biological or pandemic outbreaks and mass dispensing. In addition to the incorporation

of stochasticity of client arrival and service distribution into the model, it also accommodates the following factors:

- The clinic model can be represented as an n -server system with queueing; transmission can occur between clients or between clients and staff. (In a real emergency, staff members will be given

medical countermeasures to protect them from the disease prior to their assignment to POD services. However, a medical countermeasure does not provide 100% protection; each staff member still has a small probability of being infected by clients.)

- The intraclinic infectivity between clients and staff can vary.
- If symptomatic individuals are not triaged out properly during the initial screening, they could infect other people inside the POD. The system allows users to observe the effect of triage and screening errors, determine improved strategies for triage and screening, and establish guidelines for mitigating the spread of disease because of such errors.
- Inhomogeneous mixing within the community is possible.
- The infectious, asymptomatic, and symptomatic individuals can infect at various rates.

Figure 3 contrasts the triage accuracy with respect to the symptomatic proportion, when simple mass-action incidence infection is considered [6,33]. This analysis assesses errors in triage and their infection consequences. It provides estimates for POD planners and epidemiologists to help determine the level and expertise of triage that should be in place with respect to the transmission coefficient. It also allows for scenario-based comparison of effective POD design.

Such analyses may influence the selection of dispensing modalities. Specifically, over the past few years, we have observed more use of drive-through PODs for infectious disease prophylactic dispensing (e.g., seasonal flu vaccination for communities and the H1N1 mass vaccination in 2009 and early 2010). In January 2008, a hepatitis A confirmation of a grocery worker triggered the prophylactic vaccination of 10,000 residents in Erie County in New York who were potentially exposed to the disease, costing the county's public health agency at least \$500,000. The health department dispensed the first vaccination in February when it set

up a stationary clinic (walk-through POD). Because of the medical logistics and infectious nature of the disease, some people had to wait for hours in frigid temperatures. In September 2008, the health department used a hepatitis A follow-up drive-through POD to provide the required second shot of vaccination. The POD was also the first test of the county's "drive-through" plan. The drive-through process is quick, efficient, and convenient, and minimizes the potential of intrainfectivity [25].

Supply Chain Management: Demand, Supply, Fulfillment, and Partnership

Although supply chain management during a disaster response mirrors that of business supply chain management, damaged or destroyed infrastructure force the use of *ad hoc* solutions that limit the effectiveness and efficiency of the operation.

Demand management can be extremely difficult due to the fluidity of the population and the potential collapse of the supporting infrastructure. Problems vary depending on the nature of the disaster. In the event of an infectious disease outbreak, as in the recent H1N1 event, when there is not a sufficient supply of medical countermeasures for the affected populations, predicting and allocating the proper distribution across the nation becomes critical, but is highly stochastic and uncertain. Decisions can have a major impact on overall infectivity and mortality rates. In the same manner, demand within an earthquake zone fluctuates rapidly due to the movement of people fleeing from one site to another. And the time it takes to implement an effective response can be critical to the survivors of the affected population.

Within the United States, an act of terrorism (or a large-scale natural disaster) targeting the US civilian population will require rapid access to large quantities of pharmaceuticals and medical supplies. Such quantities may not be readily available unless special stockpiles are created. No one can anticipate exactly where a terrorist will strike and few state or local governments have the resources to create sufficient stockpiles on their own. Therefore, a national

Figure 3. The graph shows the triage accuracy versus symptomatic proportion and the importance of using the SEPAIR six-stage propagation model, because it allows us to examine the effect of implementing triage accuracy. The graph shows the number of intra-POD infections (vertical axis) under different triage accuracy and symptomatic proportions (horizontal axes). The throughput is 36,000 over a period of 36 h. The contact number is 193 (for outer-POD disease propagation), and the transmission coefficient is $0.18E^{-5}/\text{min}$. The incoming percentage for susceptible is 95%, and for infectious is 5%. The mean dwell time is one day for both exposed and infectious and three days for asymptomatic and symptomatic.

stockpile has been created as a resource for all.

The CDC's SNS is a national repository of antibiotics, chemical antidotes, antitoxins, life-support medications, IV administration, airway maintenance supplies, and medical/surgical items to protect the American public if there is a public health emergency (terrorist attack, flu outbreak, earthquake) severe enough to cause local supplies to run out. Once Federal and local authorities agree that the SNS is needed, the SNS will supplement and resupply state and local public health agencies anywhere and at anytime within the United States or its territories.

The SNS is organized for flexible response. The first line of support lies within the immediate response 12-h Push Packages. These are caches of pharmaceuticals, antidotes, and medical supplies designed to provide rapid delivery of a broad spectrum of assets for

an ill-defined threat in the early hours of an event. These Push Packages are positioned in strategically located, secure warehouses ready for immediate deployment to a designated site within 12 h of the federal decision to deploy SNS assets. These 12-h Push Packages have been configured to be immediately loaded onto either trucks or commercial cargo aircraft for the most rapid transportation. Concurrent to SNS transport, the SNS Program will deploy its Stockpile Service Advance Group (SSAG). The SSAG staff will coordinate with state and local officials so that the SNS assets can be efficiently received and distributed upon arrival at the site.

If the incident requires additional pharmaceuticals and/or medical supplies, follow-on vendor managed inventory (VMI) supplies will be shipped to arrive within 24 to 36 h. If the agent is well defined, VMI can be tailored to provide pharmaceuticals,

supplies and/or products specific to the suspected or confirmed agent(s). In this case, the VMI could act as the first option for immediate response from the SNS Program.

The SNS Program works with governmental and nongovernmental partners to upgrade the nation's public health capacity to respond to a national emergency. Critical to the success of this initiative is ensuring capacity is developed at federal, state, and local levels to receive, stage, and dispense SNS assets.

In our work on modeling and optimization of public health infrastructure and mass dispensing strategies [5,6], we describe the importance of collaboration among federal, state, local, and private sectors for successful response to large-scale emergency scenarios, and report public/private solutions for meeting the SNS dispensing requirements as prescribed within the Cities Readiness Initiative program.

Communication and Public Information

Communication and Information Technology. Communication programs and infrastructure for emergency response are discussed in detail in the article titled *Public Health, Emergency Response, and Medical Preparedness III: Communication Infrastructure*. Communication efforts should be coordinated, planned, and tested. Regular training on usage should be performed.

Briefly, multifaceted communication infrastructures are needed for effective medical and emergency response. Two-way communication lines must be kept open between emergency/medical responders and commanders for coordination and facilitation of the response effort; broadcast communication lines must be available to inform the general public about medical precautions and available services; and phone service and call answering stations must be maintained to allow the public to report critical emergency situations. Further, communication infrastructure of hospitals and related medical care entities are critical for any emergency response.

Developing and maintaining a robust communication infrastructure among hospitals, emergency medical services, and other health care facilities, as well as private medical transport companies and medical supplies vendors, is vital to providing relief operations and services during emergency situations. Such infrastructure provides the core foundation for basic knowledge sharing such as patient volume and severity, emergency room capacity, hospital bed availability; special wards availability; medical personnel specialties; transport vehicle availability; and blood, medicine, and medical supplies inventories. During an emergency situation, such critical information can be communicated to a regional coordinating control center which can assess available resources, identify surpluses and shortages, and coordinate distribution efforts. In fact, building capacity for an interoperable communication system for emergency response is identified as one of the areas that must be prioritized according to The Hospital Preparedness Program established by the US HHS.

Previous instances of emergency situations such as the September 11 terrorist incident and the Rhode Island night club fire incident have brought forth the challenges and necessity in establishing and sustaining a redundant emergency communication network. Kapucu [34] has examined the importance and challenges in establishing a coordinated interagency communication network and the role information technology serves to enhance such communication and decision making as in the context of the 9/11 terrorist incident. Challenges include interoperability among the various communication tools, reliability of the tools during emergency situations, technical limitations, barriers in interagency communication, and related aspects.

Public Information and Risk Communication. Risk communication plays a crucial role to any successful emergency response. The social challenges that arise as a result of human behavioral patterns cannot be overemphasized. During the high concern and high stress situation, the messages to the public must be concise, unified, and

coordinated. Getting correct and credible information out quickly assures the public that they can trust the authority in protecting themselves and their families. The public needs to know in a timely manner that there is a problem and the nature of the problem. Appropriate measures must be performed to curtail rumors that may cause unnecessary panic and fear, and potential unrest. Multimedia hot lines should be established to share factual information and timely updates. Educational information pertinent to the medical countermeasures and dispensing sites should be clearly stated. Finally, care must be taken to ensure that vulnerable and special-need populations are served appropriately.

Lessons Learnt and Continued Challenges

Our Experience through Anthrax Drills and Actual Vaccination Events. Our experience illustrates that by combining mathematical modeling, large-scale simulation, and powerful optimization engines and coupling these with automatic graph-drawing tools and a user-friendly interface, we can design and implement a fast and practical emergency response decision support tool that can run on a wide range of computing platforms, including personal digital assistants (PDAs) for real-time usage. The system RealOpt, developed in collaboration with CDC SNS investigators, offers public health emergency coordinators the following capabilities:

1. Determine strategically most effective locations for POD facilities to best serve the affected population.
2. Design customized and efficient POD floor plans via an automatic graph-drawing tool. Users can design and compare various floor plans to determine the trade-offs in personnel usage as well as operations efficiency.
3. Determine optimal labor resources required and provide the most-efficient placement of staff at individual stations within the POD. The resulting staffing plans maximize the number of individuals who can be treated, minimize the average time patients

spend in the clinic, and equalize utilization across clinic stations.

4. Perform disease propagation analysis, understand and monitor the intra-POD disease dilemma, and help to derive dynamic response strategies to mitigate casualties. The what-if analysis and worst-case scenarios can also equip epidemiologists with knowledge that may assist emergency planners in testing alternative POD facility layouts, assess batch size for patient orientation, and analyze the trade-offs between POD throughput operations and degree of infectiousness.
5. Assess current resources and determine minimum needs to prepare for readiness in emergency situations for their regional population.
6. Carry out large-scale virtual drills and performance analyses, and investigate alternative strategies.
7. Train personnel, and design emergency exercises with a variety of dispensing scenarios. Such training exercises could be used to quickly get new emergency preparedness planners up to speed and to keep existing planners sharp.

The computational advances also provide flexibility to quickly analyze design strategies and decisions, and can generate a feasible regional dispensing plan (with a network of cost-effective PODs, each operating at various throughput rates and utilizing various dispensing modalities) based on the best estimates and analyses available, and then allow for reconfiguration of various PODs as the event unfolds.

Some of the regional planning and operational analysis reveal that

1. sharing labor resources across counties and districts within the same jurisdiction is important;
2. the most cost-effective dispensing plan across a region consists of a combination of drive-through, walk-through, and closed PODs, each operating at a throughput rate that depends on the surrounding population density, facility type, and labor availability;

3. the optimal combination of POD modalities changes according to various facility capacity restrictions and the availability of critical public health personnel;
4. an increase in the number of PODs in operation does not necessarily increase the total number of core public health personnel needed;
5. optimal staffing is nonlinear with respect to throughput, thus we cannot estimate the optimal staffing and throughput by simply using an average estimate;
6. depending on the population, an “optimal” capacity that provides the most effective staffing exists for each POD location. If a POD is operating above its optimal capacity, reduction in capacity (and thus hourly throughput) eases the crowd-control tasks of law-enforcement personnel and helps to minimize potential operational problems inside the POD.

RealOpt has been used successfully by over 2000 public health and emergency directors and coordinators in planning for biodefense drills (e.g., anthrax, smallpox) and pandemic response events in various locations in the United States since 2005. It has also been used for dispensing clinic design and staff allocation for the recent H1N1 mass vaccination campaign. Users have tested various POD layouts, including drive-through, walk-through, and closed PODs. Because of the system’s rapid speed, it facilitates analysis of what-if scenarios, and serves not only as a decision tool for strategic and operational planning, actual drill preparation, and personnel training, but also allows dynamic reconfigurations as an emergency event unfolds. In addition, it supports performing “virtual field exercises,” offering insight into operation flows and bottlenecks when mass dispensing is required.

Continued Challenges and the Need for Multilayered Protection. The ability to analyze planning strategies, compare the various options, and determine the most cost-effective combination dispensing strategy

are critical to the ultimate success of mass dispensing.

The federal government continues to seek advances in this challenging area. In the recent Executive Order, signed on December 30, 2009 by the President of the United States, a policy was setup to plan and prepare for the timely provision of medical countermeasures to the American people in the event of a biological attack in the United States through a rapid federal response in coordination with state, local, territorial, and tribal governments. The policy seeks to (i) mitigate illness and prevent death; (ii) sustain critical infrastructure; and (iii) complement and supplement state, local, territorial, and tribal government medical countermeasure distribution capacity.

Specifically, the executive order stipulates that the federal government shall pursue the establishment of a national US Postal Service medical countermeasures dispensing model to respond to a large-scale biological attack with anthrax as the primary threat consideration. Further the federal government must develop the capacity to anticipate and immediately supplement the capabilities of affected jurisdictions to rapidly distribute medical countermeasures following a biological attack by establishment of a federal rapid response capability. The executive order also asks for Continuity of Operations where the federal government must establish mechanisms for the provision of medical countermeasures to personnel performing mission essential functions to ensure that mission essential functions of federal agencies continue to be performed following a biological attack.

Postal delivery of medical countermeasures has been discussed in detail in Wein [35]. Because postal workers deliver mail service to all households on a regular basis, the possibility of their usage for the first 12-h initial dispensing is appealing. This will allow time for the establishment of PODs for continued dispensing service. The availability of personnel during crisis can be volatile, as articulated in medical surge article (see *Public Health, Emergency Response, and Medical Preparedness I: Medical Surge*). However, such a multilayered dispensing

plan allows flexibility in response as well as leveraging and integration of heterogeneous resources for maximum coverage and outcome. Postal and POD distribution strategies require different levels of security; their trade-offs and complimentary characteristics should be carefully analyzed.

LARGE-SCALE DISASTER RELIEF EFFORTS

Large-scale disaster (humanitarian) relief efforts (e.g., in response to earthquakes, hurricanes, forest fires) where homes are destroyed, critical infrastructures are damaged, and tens of thousands or millions of people's lives are affected, require rapid establishment of "*service constructs*." These service constructs serve as home shelters for the population being displaced; as distribution nodes for receiving supplies for on-the-ground responders; as dispensing sites for handing out food and water to the affected population; and as hospital tents for medical care of the sick. In the aftermath of such an event, the medical surge requirement is acute (see ***Public Health, Emergency Response, and Medical Preparedness I: Medical Surge***), evacuation orders are highly probable (see ***Public Health, Emergency Response, and Medical Preparedness IV: Emergency Evacuation***), and the need for effective communication and coordination for humanitarian relief effort is crucial (see ***Public Health, Emergency Response, and Medical Preparedness III: Communication Infrastructure***).

We highlight below various issues that are prominent within disaster relief efforts.

Network of Service Constructs, Staffing and Resource Constraints, Opportunistic Disease Spread, and Supply Chain Management

The scope and complexity of establishing service constructs (for food and water, shelters, and medical care etc.) are very similar to those for large-scale mass dispensing efforts (as described in previous sections in this article). Past disaster relief efforts such as in the aftermath of the 2010 earthquake in Haiti highlight the daunting challenges as

the regional response must rapidly establish (in an *ad hoc* manner) dispensing and distribution networks. Many elements discussed in the section titled "A Systems View of Mass Dispensing Operations: Integrating All the Elements" on mass dispensing and population protection come into play. Further, the lack of water, electricity, shelters, poor sanitation, and the existence of at most a barebones critical infrastructure present enormous challenges.

Staffing and resources are often under severe shortage where *ad hoc* skills and just-in-time training are provided. Skilled workers such as those with medical background, logistics and operational, and security experiences may often be deployed from other countries and nonprofit organizations to help with rapid response, relief, and rebuild mission.

Crowded, unsanitary conditions in improvised refugee shelters could spread illnesses such as typhoid and measles. Thus, mass prophylactic treatments are often needed to prevent disease spread, even though illness and infections can still be a threat to survivors. Puddles of filthy water accumulated near service constructs may become a breeding ground for mosquitoes. That, in turn, may lead to the spread of deadly diseases and epidemics such as dengue, malaria, and cholera. Disease mitigation and facility layout strategies are absolute critical tasks to the livelihood of these survivors.

In disasters, suppliers and stakeholders can be very diverse, and there is usually no unifying business and operating theme to manage them. Further, unsolicited and unwanted donations can burden the management team, causing overload of arrivals at sea or airports, or congesting the warehouses [36–38].

Routing of available and necessary goods from entry ports (sea or air) to affected sites can pose daunting challenges. Efficient usage of potentially limited sea/air space and landing sites, available roads, vehicles, fuels, drivers, and materiel handling equipment at the receiving ends are all uncertain and unreliable. Food safety, sanitation hygiene, and opportunistic looting further complicate the process.

Effective coordination of multiple humanitarian agencies, in addition to military, government, and private entities, is of great importance in response to disasters. This is both a challenge and an opportunity given the differing missions, histories, and expertise of these institutions.

Coordination among Different Stakeholders

Disaster and humanitarian operations often have a large number and variety of stakeholders and multiple organizations operating in the same place simultaneously but without (formal) coordination. A loosely coupled coordination of different aid agencies, suppliers, and local and regional actors, each with their own way of operating and own organizational structures, can work charmingly yet it can also pose discord [39]. The different political agendas, ideologies, and religious beliefs and the need for appeal to public for donations and media attention complicate the work. Perhaps, the greatest challenge here lies in aligning these organizations properly without compromising their mandates and beliefs. Further, people from different cultural background may have different traditions that may hinder the communication and coordination between organizations [40]. As seen in the recent Haiti event, operational and organizational differences can also create frictions and misunderstanding among various responding nations, thus masking the effectiveness of the operations.

Sometimes, affected areas may not be reachable due to political reasons. For example, after the 2005 South Asian Tsunami, the Indonesian government felt compelled to allow free entry in a region that had been very restricted for a long time. This caused a huge influx of personnel from humanitarian organizations, *ad hoc* organizations and volunteers on sites, overcrowding the sites.

Risk and Uncertainty

Personnel working within a disaster response environment are often exposed to destabilized infrastructure [37,38]. Not only do they need to work in facilities or areas that are physically damaged, the

social effect taking place after a disaster could often become overwhelming. Many disasters such as tsunamis and earthquakes have aftereffects that could further cause panic or disruption to response operations. Uncertainty in risk, in when the suppliers will arrive and where, in the amount of supplies that are available, in the overwhelming demand needed by the affected population, add layers of anxiety and stress to these on-the-ground workers. “Disaster relief supply chain” shows the extremes of a trend toward more uncertainty and risk prevalent in today’s global business supply chain.

Media Exposure

Disaster events often have high exposure to the media. However their relationship is described by some as a love-hate one [40]. On the positive side, high exposure to the media means more public attention on the affected areas. This often translates into more donations and general support. However, mass media is short-sighted and tends to be more interested in catastrophic events while putting less focus on long-term humanitarian and relief effort. There is a need to educate and collaborate with news media personnel on disseminating long-term challenges and efforts to the general public. In recent years, some improvement has been seen as news media and public have been made aware of response failures in the emergency responses related to Hurricane Katrina and other natural disasters, and the high-profile public scrutiny of the federal and local response effort. In general, appropriate media usage can educate the public and help spread word of the situation so as to garner financial donations that are much needed in any disaster response scenario.

SUMMARY

Optimization, Simulation and Dynamical Systems Methodologies

Operations research, with its roots in defense and military operations, has a natural place in emergency response planning and execution. Optimization, stochastic simulation,

systems modeling, and decision analysis approaches are routinely used to plan for and/or aid in analyzing a broad spectrum of emergency responses as a result of natural or man-made disaster [2,6,12,41,42]. Specifically, Green and Kolesar [42] traced the history of operations research and management science applications in emergency response, with a particular focus on the work done in New York City between 1969 and 1989. Many projects were undertaken by a group of researchers as part of the New York City-RAND Institute (NYCRI) initiative. These included applications to ambulance, fire, and police car location and deployment.

Resource allocation, scheduling, facility location, vehicle routing, inventory control, and transportation logistics in emergency response have all been formulated into optimization models. Among the resource allocation models, Fiedrich *et al.* [43] used dynamic optimization model for the initial search-and-rescue period after a strong earthquake. Branas *et al.* [44] used a trauma resource allocation model for ambulances and hospitals. Tzeng *et al.* [45] presented a multiobjective optimal planning model for designing relief delivery systems. The three goals are minimizing the total cost, minimizing the total travel time, and maximizing the minimal satisfaction during the planning period. Yan and Shih [46] used a time-space network model (based on an integer network flow problem with side constraints) to minimize the length of time needed for emergency repair, with related operating constraints for emergency repair work team scheduling.

Lee *et al.* [2,5] investigated resource allocation, staffing, facility location, and multimodality mass dispensing strategies and emergency response for biodefense and infectious disease outbreaks. Some of the integer programming instances have on the order of 10 million variables and the authors provided rapid solution engines to arrive within 5% to optimality under 3 min. Zhang and Yang [47] presented an optimization model and algorithm of a facility location problem in a perishable commodities emergency system. Doerner *et al.* [48] presented a model for multiobjective decision analysis with respect to

the location of public facilities such as schools in areas near coasts, taking risk of inundation by tsunamis into account. Coskun and Erol [49] used an integer optimization model to decide locations and types of service stations, and regions covered by these stations under service constraints in order to minimize the total cost of the overall system. The model can produce optimal solutions within a reasonable time for large cities having up to 130 districts or regions.

Many authors present routing and transportation studies: Harewood [50] used a multiobjective version of the maximum availability location problem to determine emergency ambulance deployment. Wang *et al.* [51] analyzed and proposed the concept of postearthquake road safety, dividing emergency vehicle routing choice and optimization problem into two decision-making stages: pretrip and en route. Sheu [52] used a hybrid fuzzy clustering-optimization approach to study the operation of emergency logistics codistribution when responding to urgent relief demands in the crucial rescue period. Yi and Kumar [53] presented a metaheuristic of ant colony optimization for solving a logistics problem arising in disaster relief activities. Yuan and Wang [54] presented two mathematical models for path selection in emergency logistics management. The models include actual factors in time of disaster. Liu and Zhao [55] modeled an emergency materials distribution problem in an antibioterrorism system as a multiple traveling salesman problem.

Simulation has been used in numerous public health and medical preparedness topics, including evacuation, resource allocation and patient flow, routing in emergency medical services and surge planning, and disease propagation analysis.

Simulation has also been used in resource allocation and patient flow [2,3,24,56–60], and in the area of pandemic response strategies and mitigation [2,3,5,6,33,56,58,61–66]. It has found many applications in routing in emergency medical services and surge planning [62,67–69].

As modelers attempt to incorporate more realistic dynamics into epidemiology and disease propagation models (such as

stochasticity, nonexponential waiting times, sample-path dependent events, and demographical and geographical data), more flexible tools, such as individual-based stochastic simulations, are preferable. Although simulation is a powerful approach, the resulting models are often mathematically intractable, and require advances in computational strategies [6,28–31,33,70–72].

The discipline of dynamical systems, mostly differential equation systems, provides the principle methods of modeling in classical mathematical epidemiology [26,27]. It has also been used to analyze strategies and policies. Wein *et al.* [9] used a system of differential equations to model the effects of different policies in response to an anthrax bioterror attack. The system includes an atmospheric dispersion model for the spread of the bacterium causing anthrax, an age-dependent dose-response model for the impact of treatment on an individual, a disease progression model to capture the stages through which an infected individual goes, and a set of two-stage queueing systems for antibiotic distribution and hospital care. Kaplan [8] imbedded the evaluation of vaccination logistics policy within a disease propagation model and compared strategies of traced vaccination, mass vaccination, and the mixed response advocated by the Centers for Disease Control. Eichner [73] developed a deterministic model for evaluating impact of different intervention strategies during pandemic influenza. The model is based on over 1000 differential equations which extend the classic SEIR model by clinical and demographic parameters relevant for pandemic preparedness planning. The model aims to operate with an optimal combination of precision, realism, and generality. Wu *et al.* [74] developed models to demonstrate that a prepandemic vaccine allocation policy that allocates vaccine to each state in proportion to the population size is not the most efficient. In fact, an inequitable strategy that allows no allocation to some regions while the sufficient vaccines being allocated to other regions demonstrates larger benefit. However, if considering other strategy selection criteria such as simplicity, robustness, and equity, the current prorata policy is a good compromise.

Integrated Approaches, and Information and Decision Support Systems

The burden of responding to a public health or medical disaster is multifaceted and a genuine test to the sustainability of critical infrastructure. Negotiating emergency operations is especially difficult due to interagency goal conflicts, differences in organizational culture and bureaucratic constraints, discrepancies in situation assessment, scarcity of resources, and organizational complexity. Nevertheless, interplay among many agencies is critical, and consequently, integrated approaches, and information and decision support systems prove to be very beneficial as part of the solution strategies [75–80].

Iakovou and Douligeris [81] presented the development of IMASH, an Information Management System for Hurricane disasters. IMASH is an intelligent integrated dynamic information management tool, capable of providing comprehensive data pertaining to emergency planning and response for hurricane disasters. Popp *et al.* [82] developed information analysis tools for an effective multiagency information-sharing effort.

Zografos *et al.* [83] described an integrated framework consisting of a data management module, a vehicle monitoring and communication module, and a modeling module, for managing emergency response of the electric utility companies. The framework integrates a GIS system with a decision-making modeling module to deliver solutions in real-time that optimize deployment of the available emergency resources. El-Anwar *et al.* [84] presented the development of an automated system to support decision makers in optimizing postdisaster temporary housing arrangements. The system has been integrated in MAEviz and provides the capability of optimizing a number of important objectives, including minimizing negative socioeconomic impacts, maximizing housing safety, minimizing negative environmental impacts, and minimizing public expenditures.

Bui [85] proposed a framework for developing a global information network (GIN). The application would incorporate four factors that affect the design of a GIN: nature of

disaster relief operations, negotiation styles of participants, social/cultural/organizational characteristics of participants, and resource availability. Such a framework could provide a set of basic metrics/factors to characterize any disaster situation. GIN would use high-speed internet as backbone, it includes a command center where the disaster management team would be, and telecommunication channels that connect to expert advice groups from around the world. The GIN would also be linked to an array of data and knowledge base warehouses.

NYU's PLAN C is an innovative tool for emergency managers, urban planners, and public health officials to prepare and evaluate Pareto-optimal plans to respond to urban catastrophic situations. Doheny and Fraser [86] described a software tool for modeling the decisions that people make in emergency situations in offshore environments. It can be used to predict the likely behaviors of a population in hazardous situations and help evaluate the effectiveness of emergency procedures and training.

Mondschein [87] reviewed the use of spatial data by environmental managers and emergency responders who are charged with the responsibility to perform hazard assessments, identify the location of toxic and hazardous materials, deploy emergency resources, and review demographic data to ensure the safety of the public and the surrounding communities.

In our own work, the decision support system RealOpt combines OR modeling techniques, novel and large-scale computational engines, sophisticated graph-drawing tools, 3D geographical spatial information with federal census data, and demographic and socioeconomic data for operational and strategic planning, and policy analysis. RealOpt allows public health emergency coordinators to (i) determine locations for service facilities setup; (ii) design customized, efficient floor plans for each facility via an automatic graph-drawing tool; (iii) determine (in real-time) optimal resource allocation through advanced computational techniques in simulation and optimization; (iv) monitor intrafacility disease propagation through a novel disease propagation model,

and derive dynamic response strategies to reduce the spread of disease and mitigate the risk of casualties; (v) assess resources and determine minimum needs to prepare for treating regional populations; (vi) carry out large-scale virtual drills and performance analyses, and investigate alternative dispensing strategies; and (vii) design a variety of dispensing scenarios and emergency-event exercises to train personnel [2,3,5,6,10,33].

Challenges

Modeling and optimizing public health infrastructure involve elements of resource allocation under risk, uncertainty, and time pressure; large-scale supply chain management; transportation and operational logistics; and medical treatment and population protection. The operations must be supported by an effective communication infrastructure. There is a necessity for vertical and horizontal integration and communication, where federal, state, local, tribal, territorial, private, and business stakeholders work toward a common goal of a resilient public health system. The infrastructure must be *flexible, scalable, sustainable, and elastic* to support an effective and timely response, and to mount rapid recovery and mitigation operations.

The 2007 Homeland Security Presidential Directive-21 (HSPD-21) [88] established a National Strategy for Public Health and Medical Preparedness, which builds upon a four pillar framework—threat awareness, prevention and protection, surveillance and detection, and response and recovery. It aims to transform our national approach to protecting the health of the citizens against all disasters. Although the four pillars were developed initially to guide the efforts to defend against a bioterrorist attack, they are applicable to a broad array of natural and man-made public health and medical challenges, and are appropriate to serve as the core functions of the strategy for public health and medical preparedness.

Public health and medical preparedness continue to shower challenges to the scientific community. Some critical issues include (i) realistic systems modeling; (ii) intractability of large-scale instances;

(iii) interdependencies among multiple critical components/agencies; and (iv) the importance and necessity for end-to-end systems modeling and design. Technological advances are needed to allow for complex realistic modeling while providing users with affordable computational power that result in decision systems that are practical for actual scenario-based analysis. The effective integration and alignment of care personnel, facilities, and equipment and supply for optimal outcome remains essential. Capability to solve large-scale resource allocation and location problems is a must. Tracking of disease and designing and implementing dynamic mitigation strategies will have a tremendous impact on population protection. Supply chain management needs to be dynamic, and multiagency partnership models should be developed. Information sharing and management, and risk and communication strategies continue to evolve. Multimodality integration of technologies and reliable dissemination are critical. Policy and coordination among different stakeholders across country borders need to be studied and potentially streamlined. While many issues relate to operational and strategic planning, many others involve policies, risk management, security, public communication, and cultural and human behavior.

The key to success is flexibility and adaptability—in staffing, operations strategies, coordinating and communications strategies, and the willingness (for multiple agencies) to collaborate. Initial plans must be put in place and executed rapidly, and yet allow reconfiguration on the fly as an event unfolds.

Acknowledgments

Part of the material and results reported herein are based on our work in this area and interaction with public health agencies, and discussion with many state and federal public health and emergency response experts. While there are many people to thank in this multiagency and multidisciplinary collaboration, the authors would like to specially thank Dr. Jacquelyn Mason of the CDC, and Tom Tubesing, formerly of the CDC, Dr. Lawler

and Dr. Mecher at the Homeland Security Council in the White House, William Glisson at ESI, Bernard Hicks at DeKalb Emergency Preparedness Department, and the many public health and emergency managers throughout the nation. We also acknowledge the funding from the CDC. The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

INTRODUCTION

Medical and public health systems must prepare for major emergencies or disasters involving human casualties. Such events will severely challenge the ability of health-care systems to adequately care for large numbers of patients (surge capacity) and/or victims with unusual or highly specialized medical

needs (surge capability) (see *Public Health, Emergency Response, and Medical Preparedness I: Medical Surge*). In addition, medical and public health systems can expect incidents that significantly impact their usual operations, as occurred with Hurricane Katrina. These so-called *mass effect* events can have devastating consequences for medically fragile segments of society and those living with chronic health conditions. Limited or no access to routine health-care services can cause these populations to rapidly deteriorate, producing a downstream surge of demand for acute care that can overwhelm local capabilities.

Within the United States since 2003, health-care entities as well as public health and other response partners have been directed to build redundant communications systems with multiple communication technologies that would ensure connectivity and operability in the event of a public health emergency. A significant amount of funding has been provided to the states on communication devices and the building of a redundant communication system.

By FY 2007, states health departments were required to show an operational redundant communication system that is capable of communicating both horizontally between health-care providers and vertically with the jurisdiction incident command structure as described in the tiered response system outlined in the Medical Surge Capacity and Capability Handbook and in the Hospital Preparedness Program (HPP) FY 2006 guidance. The system must link all health-related organizations that participate in the program and deemed necessary to the State and local jurisdiction health and medical response operations plan, including law enforcement, public works, and others. This system should have the ability to exchange voice and/or data with all partners on demand, in real time, when needed and as authorized in the operational plans developed by the State and local jurisdictions.

All systems must meet SAFECOM requirements for communications interoperability, as established in April 2004 by the Department of Homeland Security and introduced in the FY 2006 HPP guidance. SAFECOM defines the future requirements for crucial voice and data communications in day-to-day, task force, and mutual aid operations, and establishes parameters around owned or leased radio equipment use.

This article presents an overview of communication infrastructure needs, and findings from our recent study and evaluation of statewide emergency communication systems in Georgia. Specifically, the section titled “Emergency Communication System” describes the importance and necessity of the emergency communication system. Physical infrastructure including various phone and radio technology are described and contrasted in the section titled “Physical Infrastructure for Emergency Communication,” and communication infrastructure is highlighted. This is followed by discussion of communication-facilitated programs including Telecommunications Service Priority Program, Government Emergency Telecommunications Services, and Wireless Priority Service Program in the section titled “Communication Facilitation Programs.” The section titled “Organizational Factors in Emergency Communication” states the organizational factors that are critical to cultivate and develop a strong communication infrastructure and personnel capability. The section titled “Sociological Factors and Linkage to Human Behavior” focuses on sociological factors and human behavior. Complementing the communication network for emergency responders, the section titled “Public Information and Risk Communication” touches on the need to maintain multimedia broadcast communication technology to inform the public of safety precautions, where to seek help, and any other important public service announcements.

EMERGENCY COMMUNICATION SYSTEM

Multifaceted communication infrastructures are needed for effective medical and

emergency response. Two-way communication lines must be kept open between emergency/medical responders and commanders for coordination and facilitation of the response effort; broadcast communication lines must be available to inform the general public about medical precautions and available services; and phone service and call answering stations must be maintained to allow the public to report critical emergency situations. In this section, we focus on the communication infrastructure of hospitals and related medical care entities.

Developing and maintaining a robust communication infrastructure among hospitals, emergency medical services (EMS), and other health-care facilities, as well as private medical transport companies and medical supplies vendors, is vital to providing relief operations and services during emergency situations (see *Public Health, Emergency Response, and Medical Preparedness I: Medical Surge*; *Public Health, Emergency Response, and Medical Preparedness II: Medical Countermeasures Dispensing and Large-Scale Disaster Relief Efforts*; and *Public Health, Emergency Response, and Medical Preparedness IV: Emergency Evacuation*). Such infrastructure provides the core foundation for basic knowledge-sharing such as patient volume and severity, emergency room capacity, hospital bed availability; special wards availability; medical personnel specialties; transport vehicle availability; and blood, medicine, and medical supplies inventories. During an emergency situation, such critical information can be communicated to a regional coordinating control center, which can assess available resources, identify surpluses and shortages, and coordinate distribution efforts. In fact, building capacity for an interoperable communication system for emergency response is identified as one of the areas that must be prioritized according to The Hospital Preparedness Program established by the US Department of Health and Human Services.

Previous instances of emergency situations such as the September 11 terrorist incident and the Rhode Island night club fire incident have brought forth the challenges in

and necessity for establishing and sustaining a redundant emergency communication network. Kapucu [1] examined the importance and challenges in establishing a coordinated interagency communication network and the role information technology serves to enhance such communication and decision making as in the context of the September 11 terrorist incident. Challenges include interoperability among the various communication tools, reliability of the tools during emergency situations, technical limitations, barriers in interagency communication, and related aspects.

Physical Infrastructure for Emergency Communication

Studies have been conducted in analyzing the requirement for effective hospital communication systems. Becker [2] discussed the effectiveness of focus groups and tabletop exercises involving key stakeholders in the public health community for initial structuring of the emergency communication infrastructure. Such exercises serve as a platform for discussing the functional and performance requirements for redundant communication and the type of information to be delivered. Manoj and Baker [3] identified three categories of communication challenges from literature review: technological, sociological, and organizational. Recently, we have completed an evaluation of emergency communication infrastructure among a network of 148 hospitals in Georgia.

Below, we summarize some of our findings, and discuss the status quo and challenges faced by the health systems [4].

Communication Tools. A wide range of communication tools are used in the health-care facilities. They can be classified into three main categories: phones (such as landline, mobile phones, satellite, dedicated, and VoIP), radios (such as 700 MHz, 800 MHz, UHF, VHF, microwave, and HAM) and computer-based tools (such as email and web-based collaborating platforms). When comparing the effectiveness of the tools, some of the metrics to take into consideration are medium of communication, security, emergency reliability factors, emergency

response services, cost of installation and usage, general application in public and private domain, and technological limitation. Table 1 compares telephones used in health-care facilities.

Landlines and cellular phones are commonly used in hospitals in both daily operations and emergencies as primary communications tools due to their low learning curve and relatively low cost. However, in a disaster event, many factors could contribute to the vulnerability of these tools, such as network congestion, network structural damage as observed in natural disaster, or a carefully crafted terrorist attack with the communication system as a target. On the other hand, tools like satellite phone and dedicated phone lines require higher initial investment and higher maintenance, but demonstrate high reliability. VoIP phones have high reliance on availability and stability of broadband internet. Current statistics on usage of VoIP phones is likely to change drastically in the near future given the emerging trend of dependency toward the internet for communication.

Table 2 compares the functions and characteristics of various types of radios. Among all the hospitals in the State of Georgia, 800-HMz radio, VHF, UHF, and HAM radio are more commonly seen than other radio technologies [4]. The percentage of hospitals possessing these tools ranges from 36 to 50%. Microwave radios, in particular, offer a wide range of features for emergency communication but are currently not used for hospital emergency communications. Adoption of new technology can be slow due to the lack of financial resource as well as potential training cost in equipment usage.

Researchers continue to examine the functionality and effectiveness of some novel tools with hybrid technologies. Ammenwerth *et al.* [5] examined the usability of a multifunctional mobile information and communication system through a simulation study conducted in a model hospital environment. Holzman [6] proposed the design of a computer-based communication device that can be used for onsite patient information retrieval during traumatic situations. The purpose of the user interface is to facilitate a

Table 1. Telephony Networks Comparison [4]

Features	Landline	Cellular	Satellite	Dedicated	VoIP
Medium of communication	Metal wire Optical fiber Airwaves	Airwaves	Airwaves	Metal wire Optical fiber	Metal wire Optical fiber Airwaves
Security	Secure	Insecure	Secure	Secure	Insecure
Emergency reliability factors	Network congestion	Network congestion Infrastructure reliability	Satellite congestion	Infrastructure reliability	Network congestion Infrastructure reliability Transmission system crash
Emergency applications	Text messaging	Push to talk Text messaging Email	Text messaging Calling services	Seamless connectivity between terminals	E911 services Text messaging Calling services
Cost of installation and usage	Installation: \$50-\$75 Usage: around \$40/ month	Installation: \$25-\$50 Usage: Ranges from \$30-\$100/ month	Installation: \$200-\$2600 (Handset cost) Usage: prepaid cards ranging from \$200-\$5000	Requires specialized cable installation Applicable for high priority communication services, e.g., military applications	Free Installation Usage depends on subscription and internet connection
Strength	Ease of usage and subscription	Ease of usage and subscription Mobility	Seamless connectivity High mobility	Dedicated connection between terminals No network congestion	Wide range of applications Ease of usage and subscription Mobile connectivity

Limitations	System getting outdated owing to better features of cellular/VoIP providers Higher maintenance and service requirements	Network congestion at peak/emergency hours Service provider infrastructure and network capabilities	High cost of handset as well as usage Satellite congestion lead to service disruption	Very high cost of installation System depends on cable infrastructure Higher maintenance and service requirements	Available bandwidth Network latency Echo, reliability Quality of service Lack of technical assistance
Caller tracking	Based on caller information Tracking based on requirement	User-assisted GPS to track caller	Uses GPS recognition to track callers	Standard tracking based on requirement	Depends solely on subscriber responsibility No tracking of caller possible
Additional features	Caller ID Conferencing Voice-based services	Broadband Internet Voice-based services Text alert services Flexible calling tariff	Broadband Internet Voice-based services Text messaging E-mail	Secure call transmission	Conferencing Secured subscriber preference Location independence Advanced telephony features

Table 2. Radio Networks Comparison [4]

Features	700 MHz	800 MHz	VHF	UHF	Microwave	HAM
Frequency	700–800 MHz	800–900 MHz	30–300 MHz	300–3 000 MHz	7–38 GHz	1.6–27 MHz
Security	Digital encryption Local IP address	Digital encryption Privacy plus Private conversation	Analog direct Unintercepted communication	Digital encryption	Highest link reliability IP/data transmission protocols	Digital encryption Dual/round table transmission
Emergency networks range	Block D: 758–763 and 788–793 MHz	Public safety 21–824 MHz 866–869 MHz	156.8 MHz, 164.4 MHz	450–470, 800 MHz subband, 2500 MHz subband	7–38 GHz	148.8 MHz
Usage features	VoIP services High-speed broadband access Video for surveillance High speed in built access for MTU/MDU	Trunked radio service Computer-controlled network assignment Call monitoring Interference reduction Frequency allocation	Voice operations in repeaters and voice links Link with computer-controlled equipment Reliable telemetry link in place of expensive phone lines	Trunked frequency radio communication Computerized call/data monitoring	Cellular networks for high speed links between stations Wireless local loop systems Broadband internet Voice/data application and emergency restoration	Automatic dialer Node terminal operation Multiple scan Computer interface
Cost	Handset: \$99–\$1 000	Handset: \$80–\$1 000	Handset: \$75–\$500	Handset: \$100–\$3 000	System: \$2000 and above	Handset: \$50–\$2500

✓	Pros	Direct operation with other 700–800 MHz users No infrastructure needed for field communications Nonrepeated system Simple reliable system No audio delays	Wide area coverage Digital signaling features Interoperability Talk group creation	No special infrastructure requirements for field communications Non-repeated systems Simple reliable systems No audio delays	Physical barrier penetration. Less interference from other bands High data transmission efficiencies Widely used	More signal transmission than wired systems Immediate spread spectrum Microwave link setup for disaster situations Military use Wide ranging frequencies for transmission	Networking for amateur usage Used in emergency communication during/after disasters
	Cons	Frequencies not available in all areas Units keying up simultaneously Audio quality least preferred No warning of fading	Complex infrastructure Noticeable audio delays Loss of system coverage required in buildings Inconsistent interior communication	System must meet FCC narrow banding requirements by 2013 Limited interoperability with other agencies on 700–800 MHz Systems not seamless Analog equipment may not be available due to digital transition	Commercial licensing underway Digital transmission lessens bands for emergency amateur usage Requires advances in equipment Battery requirements for sustained communication	Free space loss Transmitter sensitivity Infrastructure requirements Multipath interference Signal-to-noise ratio considerations	Amateur licensing requirements

Table 2. (Continued)

Features	700 MHz	800 MHz	VHF	UHF	Microwave	HAM
Application	Public safety Government entities Logistics Property management Hotel Port	Public safety Amateur radio communica- tion Closed network communica- tion	Airband (aircraft) radio Amateur radio FM radio broadcasts Marine VHF radio	Emergency response in public networks Private closed circle data transmission Amateur radio	Low power radio for wireless networking within a building Long distance telephone signal transmission	Amateur radio Emergency response systems
Special features	Communication range alert Programmable frequencies CTCSS/CDCSS work group authorization	Interoperability Interference control through computerized network traffic monitoring	IP switch frequency allocation Noise synthesizer Commercial grade TCXO for tight frequency accuracy	Programmable frequencies Interference reduction techniques	Digital data transmission Superior technology for 100% data transmission capabilities Interfaced with computer	High frequency stability with built in TCXO grade modules

common platform for patient data collection and transmission so that the medical facilities can be prepared for the proper medical procedure immediately upon the patient's arrival rather than spending time on information retrieval and diagnosis. Among the various information technology applications for out-of-hospital response phase, Arnold and Levine [7] analyzed the usage of P2P wireless communication application in a hospital setting and concluded that it provides superior performance than related applications by integrating reliability, flexibility, and information security.

Communication Infrastructure. Building a reliable communication infrastructure requires not only the use of the right tool but also using the tool right. Jennex [8] proposed a model for emergency response system and discussed the imperative need for a dynamic integrated collaborative method to communicate between users and data sources and the necessity for establishing protocols to facilitate communication and to improve decision making. Related work by Jan and Hwang [9] included optimizing the topological layers of links within the design of a communication network that simultaneously minimizes cost while satisfying reliability constraints over the links.

Communication during a disaster involves the connection between multiple agents, such as a regional coordinating hospital, community emergency operations center, local EMS services, county health department, and the local police and fire department. A reliable system also requires multiple layers of communication systems. According to our analysis of hospitals in the state of Georgia [4], most hospitals have two levels of communication infrastructure built with tools that are commonly seen but are subject to damage/congestion during emergency (such as cell phones and landlines). Manoj and Baker [3] identified the multiorganizational radio interoperability issue as an important obstacle to overcome.

Communication Facilitation Programs

The Federal Communications Commission and the National Communication System

have established various emergency communication restoration systems and protocols that facilitate public as well as hospital communications during emergency situations. Below we compare three existing programs, namely, Telecommunications Service Priority (TSP) Program, Government Emergency Telecommunications Services (GETS), and Wireless Priority Service (WPS) Program.

The TSP program, a Federal Communication commission and National Communications Systems initiative, is aimed at maintaining priority over the telecommunication links (wireline and wireless) during emergency so that essential services are not disrupted in operation. This system is of vital importance to services such as disaster communication centers (911 call centers), police, fire, and so on. The enrolling criterion includes a nonrefundable fee of \$100, monthly subscription maintenance charge of \$3 per line, and enrollment in the NS/EP program. The limitations of the system include monthly subscription, renewal of the license every three years, and the lack of interoperability in case of landline disconnection or wireline provider shift.

The GETS program, a National Communication Commission initiative, is aimed at providing wireline subscriber priority and communication restoration through usage of GETS card. The enrolling requirements include subscription in the NS/EP program, and the cost of usage of the GETS card is 10c per minute within the United States. GETS is an essential program for unrestricted emergency operations with around 90% call completion rates even when the congestion factor is 8. It offers seamless connectivity at times of emergency. Some of the unique features of the system include a toll-free access number, access control through PIN number usage, failsafe access, enhanced carrier routing/alternative carrier routing, priority treatment with trunk queueing, subgrouping and reservation, and interoperability with other networks.

The WPS, a joint initiative by the Federal Communication Commission and private wireless carriers, is aimed at Wireless priority and communication restoration for authorized personnel at times of emergency. The

enrollment in the program is subjected to a federal scrutiny and is restricted to key members in Public health/safety/law enforcement and the likes. The benefits of the system include high call completion probability by NS/EP call marking, originating radio channel priority, and terminating radio channel priority by call queueing. The limitations of the system include monthly payment for service restoration and program enrollment, service being carrier dependant, and lack of system support for prepaid cell phones and TDMA technology. Since the cellular prioritizing is computerized, the call connectivity depends on the priority ranking. Although the system is currently available throughout the country, the service is carrier dependent.

In Table 3, we first analyze the operational attributes of each of these facilitation systems and then compare their effectiveness. Although the three existing facilitating programs that are sanctioned and run by the federal government and dedicated for emergency communications restoration offer some valuable features for emergency response, they are not fully utilized as our findings show low enrollment among the hospital networks [4]. Such communication facilitation programs can be invaluable during an emergency situation and should be encouraged in a national level.

Organizational Factors in Emergency Communication

Organizational factors in emergency communication involve managerial attitude toward building healthy communication systems as well as the flexibility and adaptability of an organization in terms of hierarchical reporting structure in the event of a disaster.

Adapting to novel technologies could involve a somewhat steep learning curve. It is therefore important that training and testing of emergency communication tools are emphasized from the managerial level. It is also not practical to assume that operations will function properly in a crisis. A regular testing of the communication system will improve the organization's responsiveness to crisis in the following ways:

- testing the effectiveness of training;
- familiarizing staff and workers with emergency procedures; and
- identifying further problems existing within the system, as well as organization policies.

Another important factor in emergency communication is the reporting hierarchy and decision making. Response to emergencies may require decision making to take place as they might in a flatter, more dynamic, *ad hoc* organization. While hierarchical organizations can lead to wider information gaps across the organizations, flat organizations are not easily scalable. (A hierarchical organization refers to those with more structured pyramid-like organization where one person is in charge of a functional area with one of more subordinates handling the subfunctions. Flat organization refers to an *organization structure* with few or no levels of intervening management between staff and managers.) Therefore, a hybrid organizational model needs to be developed to best utilize the two organizational approaches [3,10–12].

Sociological Factors and Linkage to Human Behavior

The social challenges that arise with communication as a result of human behavioral pattern must be considered when designing a communication system.

Confidentiality and information security are always legitimate concerns in the dissemination of medical information. These concerns are escalated in emergency situations since the setting is unfamiliar and emergency response usually involves multiple agencies and stakeholders, some of whom may use volunteers who may not understand the sensitivity of information and the need to protect patient privacy.

Emergency situations can also cause volatile emotions, which may hinder communication. Fear, stress, and other emotions can be aggravated by the lack of information. Therefore, periodic information updates are important. Hegde *et al.* [13] presented a technological solution that provides differentiated services for an agitated caller by

Table 3. Comparison Between the TSP, GETS, and WPS [4]

Features	TSP	GETS	WPS
Objective	Prioritize communication of wireline and wireless subscriber	Prioritize communication of wireline subscriber Communication restoration through usage of GETS card	Wireless priority and communication restoration for authorized personnel's
Controlling authority	Federal Communication Commission and National Communications Systems	National Communication Systems	Federal communication Commission and private wireless carriers
Enrollment requirements	Enrollment in one of the National Security/Emergency preparedness program Pay the required dues and submit requisition form After scrutiny, notify authorities for emergency restoration protocols	Enrollment in National Security/Emergency preparedness program Public health, safety and maintenance of law & order	Key federal, state, local and tribal government and critical infrastructure Personnel requirements: – Executive leaderships – Disaster response/military command – Public health/safety/law enforcement command – Public services/utilities
Cost of enrollment	Enrollment fee: \$100 Monthly charge per line:\$3	No enrollment charge Call charge: 10c/min for calls within United States	Activation charge: \$10 Monthly charge: \$4.50
Benefits	Restoration of services in essential disaster communication centers such as 911 call centers, police, fire, and so on	Essential program for unrestricted emergency operations Around 90% call completion rates when congestion factor is 8 No additional software requirements	High call completion probability Originating radio channel priority Terminating radio channel priority by call queueing

Table 3. (Continued)

Features	TSP	GETS	WPS
Limitations	Monthly payment for service restoration Revalidation of TSP authorization every three years Entire restoration structure pertains to subscribed telephone company and needs to be modified in case of phone change	Usage charge and tariff based on wireline provider Requires calls to be placed in landline for priority treatment Federal thresholds based on tariff, usage Private entities require further scrutiny	Monthly payment for service restoration and program enrollment Cannot be provisioned on prepaid cellphones Service not available on TDMA technology
Special features	Prioritizing serves as a source of National Security/Emergency preparedness	Toll-free access number PIN number access control Failsafe access Enhanced/alternative carrier routing Interoperability with other networks International calling/number translation	Computerized cellular prioritizing and priority ranking Service availability is carrier dependent High availability throughout the country Software enhancements are provided for priority restoration of services

detecting the emotional content in speech packets over a wireless network.

The lack of common vocabulary between response agencies and between organizations and victim populations makes communication even more difficult. While concerted effort has been made to improve the communication between organizations through common vocabulary, efficiency is still lacking. Social science research has been conducted to investigate common languages and principles such as icon languages for use between response organizations and the affected population. Social networks such as Twitter and Facebook are common meeting places nowadays. Such communication infrastructure can be very effective in message dissemination. However, its full effect relies on users' capability to differentiate facts from rumors, and to perform measures

according to instruction upon receiving the information.

PUBLIC INFORMATION AND RISK COMMUNICATION

While the emergency communication systems across various health systems, EMS, and emergency departments provide responders and commanders the capability to maximize their rescue and response ability and manage their available resources so as to best serve the affected population during crisis, parallel communication needs to exist to inform the public of safety precautions, where to seek help, and any other important public service announcements. Risk communication plays a crucial role to any successful emergency response. The social challenges

that arise as a result of human behavioral patterns cannot be overemphasized. During the high concern and high stress situation, the messages to the public must be concise, unified, and coordinated. Getting correct and credible information out quickly assures the public that they can trust the authority in protecting themselves and their families. The public needs to know in a timely manner that there is a problem and the nature of the problem. Appropriate measures must be performed to curtail rumors that may cause unnecessary panic and fear, and potential unrest. Multimedia hotlines should be established to share factual information and timely updates. Educational information pertinent to the medical countermeasures and dispensing sites should be clearly stated. Finally, care must be taken to ensure that vulnerable and special need populations are served appropriately.

SUMMARY

Developing and maintaining a robust communication infrastructure among hospitals, EMS, and other health-care facilities, as well as private medical transport companies and medical supplies vendors, is vital to providing relief operations and services during emergency situations. Such infrastructure provides the core foundation for basic knowledge-sharing such as patient volume and severity, emergency room capacity, hospital bed availability; special wards availability; medical personnel specialties; transport vehicle availability; and blood, medicine, and medical supplies inventories. During an emergency situation, such critical information can be communicated to a regional coordinating control center, which can assess available resources, identify surpluses and shortages, and coordinate distribution efforts. In fact, building capacity for an interoperable communication system for emergency response is identified as one of the areas that must be prioritized according to The Hospital Preparedness Program established by the US Department of Health and Human Services. The September 11 terrorist incident showcases the importance of redundancy of communication infrastructure.

Multifaceted communication infrastructures are needed for effective medical and emergency response. Two-way communication lines must be kept open between emergency/medical responders and commanders for coordination and facilitation of the response effort; broadcast communication lines must be available to inform the general public about medical precautions and available services; and phone service and call answering stations must be maintained to allow the public to report critical emergency situations. Further, each state must strive to establish an operational redundant communication system that is capable of communicating both horizontally between health-care providers and vertically with the jurisdiction incident command.

Communication tools stockpiled must be tested and emergency personnel must learn to use them properly. Communication-facilitating programs are invaluable tools, and public health and emergency health organizations must enroll in them and learn to use their functionalities for practical emergency response execution. Organization must cultivate the atmosphere of proper emergency communication training. Sociological and human factors can play a critical role in the success of such communication infrastructure.

Communication to the public is an integral feature for mounting successful response. Critical components of the public information and risk communication plan are to inform, educate, and reassure those most impacted by a public health emergency in a timely manner. During a large-scale emergency, public fear and anxiety may create a challenge to dispensing preventive medication (prophylaxis) and following guidelines to those individuals in need. An effective risk communications plan informing and reassuring the public will reduce fear and anxiety, and will be crucial for earning public confidence and cooperation for distributing and dispensing medication.

Acknowledgment

Part of the material and results reported herein are based on our work in this area and interaction with public health agencies,

and discussion with many state and federal public health and emergency response experts. We also acknowledge the funding from the CDC and the State of Georgia Department of Human Resources.

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

INTRODUCTION

In the aftermath of the September 11 terrorist attacks and the dissemination of anthrax in 2001, the ability of the U.S. healthcare system to provide an effective and coordinated response and evacuation capability to

mitigate mass casualty or complex incidents came under intense scrutiny. More recently, the devastation caused by Hurricane Katrina and the mass disruption of public health and medical services along the Gulf Coast spotlighted the need for cohesive strategies that focus on mounting effective evacuation and response for catastrophic events. Determining the most effective evacuation plan for a large public facility requires in-depth analysis of multiple interdependent and competing factors. Determining the best routes, foreseeing potential problems, addressing the chaos/panic factor, and orchestrating the evacuation are all critical aspects that should be evaluated in a well developed disaster management plan. Encouragingly, an evacuation conducted after a bomb threat at the stadium Santiago Bernabeu in Madrid, Spain, where 80,000 people were able to complete evacuation in 7 min (in comparison to prior drill results estimated 15 min) shed some light on the potential of saving many lives by careful planning and proper evacuation responses [1].

In this article, we seek to understand the elements that influence evacuation planning, issues faced by decision makers, as well as methodologies from the field of operations research that are leading to more effective planning and execution.

We will examine evacuation at both a health-care facility level and a community level. The discussion will be limited to evacuation caused by emergency scenarios, and exclude war-time evacuation.

The section titled "Emergency Evacuation" first provides the formal definition of emergency evacuation. The section titled "Factors that Affect Emergency Evacuation Planning" briefly describes the factors that affect emergency evacuation planning, including the nature of the threat, the potential extent of damage, and the risk to patients, if it relates to a health-care facility. The section titled "Issues in Hospital Evacuation" describes issues related to hospital evacuation, including facility, people, and

supporting service. The evacuation behavior is summarized in the section titled “Evacuation Behavior.” The section titled “Operations Research Methodologies” provides an overview of some of the operations research methodologies employed in emergency evacuation. Challenges in this area are highlighted in the section titled “Challenges.”

EMERGENCY EVACUATION

The early work by Quarantelli [2] provides a comprehensive report on evacuation behavior based on existing literature and evacuation data available at the Disaster Research Center at the Ohio State University. Evacuation is defined as

“...the mass physical movement of people, of a temporary nature, that collectively emerges in coping with community threats, damages or disruptions.”

It involves movement of people and equipment from unsafe areas to relatively safe places.

The scope of an evacuation refers to the general number of people affected. The scope could grow over time depending on the nature of the event. The following are some examples of escalating scope of evacuations [3]:

- defense in place, where minor adjustments are made to accommodate the event, but essentially no one is moved;
- single department/floor/unit in a venue;
- section, that is, multiple floors/units within a single building;
- entire building to another location on campus;
- entire campus evacuation;
- citywide evacuation.

Factors that Affect Emergency Evacuation Planning

The first factor affecting evacuation planning is the nature of the threat itself. Depending on the geographic location and/or time of year, communities may have a different probability for facing different natural or

man-made threats. While cities located close to the coast might be mostly concerned with seasonal hurricanes, those located on or near tectonic faults must be prepared at all times for a possible earthquake. And in high density population areas, major concerns may involve fire, hazardous material spills, or even terrorist attacks.

A second factor concerns the potential extent of damage. In the case of a fire or chemical spill, the affected area is generally smaller than for natural disasters that hit an entire geographical region. In the latter case, various facilities in the region may all be affected, and thus a large-scale evacuation is triggered (e.g., city-wide evacuation). Thus, this factor has a direct impact on the scope of evacuation.

In the event of a health-care facility evacuation, a third factor to consider is the risk to patients. Risk to patients varies depending on patients' conditions, acuity, and nature of the event. For example, in an emergency involving loss of electric power, patients in need of ventilators are more vulnerable compared to patients with mobility issues; whereas an event involving structural damage to the building may require allocating more resources to transferring patients with less mobility.

Overall, the resources demanded for evacuation is a critical issue. Indeed, evacuation requires resources of types and levels very different from routine operations. Further, structural damage (e.g., to airports and roads) or severe conditions may prohibit the transportation of much-needed supplies to the affected population or in a timely manner.

Issues in Hospital Evacuation

Traditional hospital evacuation plans involve horizontal (moving to a safer location on the same floor) and vertical (moving to another floor that is unaffected by the event) evacuations. However, full hospital evacuation requires moving patients and staff and others to a safe haven in preparation for a move to another facility.

According to Continuum Health Partners [3], a comprehensive evacuation plan addresses three basic elements: *facility*, *people*, and *support services*. Facility involves

rapidly identifying areas of the hospital that require a high priority for evacuation, areas of vulnerability, and areas that have potential risk. People involves assessing, triaging, tracking, and reconciling patients, staff, visitors, and others as they move throughout the evacuation, which is the single most important aspect of a hospital evacuation plan. Support service addresses areas such as systematic shutdown of medical gases, support of utilities and generators, telecommunication systems (see ***Public Health, Emergency Response, and Medical Preparedness III: Communication Infrastructure***), and operations logistics (see ***Public Health, Emergency Response, and Medical Preparedness II: Medical Countermeasures Dispensing and Large-Scale Disaster Relief Efforts***).

Facility. Facility issues involve rapidly identifying areas of the hospital that require a high priority for evacuation, areas of vulnerability, and areas that have potential risk.

Collaboration between nearby hospitals and health-care facilities are important in identifying facility problems and solutions. In the United States, many counties have their own emergency operation center to help facilitate communication, coordination, and transportation between facilities. However, it was reported in one study that hospitals are capable of communicating among themselves during emergency events and can successfully transfer a large number of patients into safe facilities [4].

People. Accounting for people, including patients, staff, visitors, and other personnel, is a core component of hospital evacuation planning.

Emergency situations present many difficulties that are not faced during regular operations. For example, in the event of electric power outage, basic tracking and updating of patient records may be difficult without availability of the computer system. Cases have been reported as early as the mid-1980s where patient records were not updated until days after the event, resulting in confusion among caretakers [5]. This problem can

become very acute when electronic medical records are in use throughout the facility. It is recommended that a paper record system be in place to record patient information, their attending physician information, accepting facility and accepting physician as well as discharges, diagnostic tests, procedures, equipment needed, mode of transport, time of departure and arrival for transferring [3,6].

It is also necessary to identify and prepare patients for evacuation off the in-patient unit by preparing necessary medical information, medical records, and medications for accepting facility to carry on continuous care when patients are transferred [3].

On the basis of patient record, a triage system must be in place to determine the urgency of each patient case and prioritize transferring of inpatients. It is often required to facilitate the evacuation process. To achieve the maximum number of evacuated patients in the shortest time, it is common practice that hospitals evacuate the most mobile patients first. However, when faced with limited resources, hospitals tend to transfer the most care-intensive patients first.

In terms of staff, research has suggested that each evacuation area should designate a Unit Evacuation Leader who should coordinate the evacuation of the entire area. The role of volunteers in emergency evacuation has been mentioned.

Support Service. Support service addresses processes such as systematic shutdown of medical gases, assessing and maintaining utilities, emergency generators, telecommunication systems, and emergency logistics.

It is possible that an emergency event arises from nonstructural damage scenarios such as a water or power outage. In this case, hospitals should have backup power system that can operate until patients can be transferred safely. (All business-critical computer systems, including financial and clinical systems, should of course have offsite backup.)

Normal communications could be disrupted with structural damage of the landline or cellular towers. Emergency communication infrastructure should be put in place to plan for unforeseeable

events (see *Public Health, Emergency Response, and Medical Preparedness III: Communication Infrastructure*).

A variety of transportation modes can be deployed. These include helicopters, buses, trains, ambulances, or family vehicles. The choice of different transportation modes largely depends on the condition of the patients. Decisions have to be made based on an assessment of the potential benefit of transport versus the potential risks.

Evacuation on this scale is expensive, as it entails extra staffing, EMS utilization, and overnight housing. In the decision making process, a cost–benefit analysis is often used in evaluating different evacuation plans. However, it is difficult to put a monetary value on patients' lives. Just as with many events within an emergency response, the key lies in optimizing the operations under limited resources.

Evacuation Behavior

For general community evacuation, one critical element concerns evacuation behavior, including factors that affect decision making and traffic pattern of evacuees.

There has been mounting interest in gaining a better knowledge of how individuals in emergency situations behave when evacuating from a venue. One study suggests that a person's total evacuation process can be divided into four phases: assessment of the situation, movement, path-finding, and evacuation [7]. The variations with respect to time of individuals' progression through different phases of evacuation were observed in a study of the 1993 bombing of the World Trade Center [8]. People in a panic-causing emergency typically show stubborn and sub-optimal behavior, such as over-crowding and congestion [9]. Their research shows that panic may cause people to become oblivious to alternative (preferable) evacuation routes as their instincts are to follow the crowd and get to the head of the pack. The effect of structural parameters on individuals' ability to successfully egress has also been studied. Research shows that egression time increases as corridor complexity increases, and decreases if clear signage is provided [7]. Although emergency signs are

believed to play an important role in ensuring public safety in facilities during emergencies, in practice, specific and clear standards for placing emergency signs have not yet been established.

Much research has been done on evaluating evacuation decision making. Fischer *et al.* [10] investigated the factors and circumstances in which citizens would actually evacuate when receiving a warning from the authority. On the basis of survey data collected after a fire incident at Hamilton Distributing Company in Ephrata, Pennsylvania on May 1, 1990, it was found that residents are most likely to evacuate if they are ordered to do so, if they are contacted frequently by authority, if past warnings were accurate, and if dependent children were at home.

Lindell *et al.* [11] collected survey data from 2002 Hurricane Lili evacuation from some counties in Louisiana and Texas to investigate factors that affect evacuation decision for households. Some of the major findings are as follows:

- local news media is the most extensive source of information for hurricane development;
- the environmental cue is the most important factor in making an evacuation decision, followed by personal experience and social cues;
- evacuation impediments include job requirement and traffic congestion.

Drabek [12] looked at the difference between public response versus response made by business executives of tourist firms when making a disaster evacuation decision. It was found that most business executives have evacuation plans although they may vary greatly in term of preparedness. Managerial decision making is parallel to public response. Five key differences between public response and business response are influence and planning, firm versus family priorities, shelter selection, looting concerns, and media contacts.

Cohn *et al.* [13] interviewed both residents and public officials from western United States on the issues and problems they are facing when dealing with wildfire evacuation.

A contrast of interests was found between the two parties when making evacuation decisions through stages. For example, during anticipation stage, the public officials' greatest interest lies in ensuring safety of the entire community. Residents tend to gauge the seriousness of the threat, preparing appropriately and at the same time maintaining a normal life. This contrast in interest pertains throughout all stages of evacuation: anticipation, warning, displacement, notification, and return and recovery. Keeping these differences in mind may better assist authorities for designing effective evacuation planning.

Aguirre [14] surveyed the population in Cancun, Mexico during Hurricane Gilbert in 1988 and identified factors that affected their evacuation behavior. A post disaster survey was conducted one week after the impact and collected responses from 431 individuals, among whom 25% of them were evacuated during the impact. Family and friends tended to be the first stop shelter evacuees sought. The survey result also demonstrated that environmental context and physical characteristics of residence greatly impacted the perception of risk, which subsequently influenced the evacuation behavior. Other factors, such as socioeconomic factors have also been studied.

Other researchers have been concerned with the logistics aspects of evacuation, such as cost and transportation. Dow and Cutter [15] examined the demand of transportation infrastructure during the 1999 Hurricane Floyd evacuation. It was found that about 65% of South Carolina residents decided to evacuate. The study revealed three factors that contributed to the traffic congestion on interstate highways: (i) 25% of families took two or more cars for evacuation; (ii) only half of those with a map made an effort to find alternative routes instead of staying on the interstate; and (iii) majority of evacuees made extra trips that were unnecessary in order to get away from the hurricane.

Evacuation without guidance on timeline and traffic routes often proves to be deficient. Even in well-planned scenarios, as in the September 2005 evacuation of Texas citizens from Hurricane Rita, major problems can

ensue. Although the governor had announced a staggered schedule of evacuation for various districts and population zones within a 24-h period, well in advance of the storm's possible landfall later in the week, it was still not early enough to ensure that all residents could evacuate safely in advance of the storm. This reinforces the key elements of emergency response—that careful planning with procedural and policy guidelines must be in place, and that improvised and dynamic reconfiguration must be executed as the event unfolds.

OPERATIONS RESEARCH METHODOLOGIES

Much research has been done on emergency evacuation simulations. Usually, the focus is on one of the following four aspects of emergency evacuation: simulation methodology, human factors, model scale, and model speed.

Zheng *et al.* [16] studied seven methodological approaches: cellular automata models, lattice gas models, social force models, fluid-dynamic models, agent-based models, game theoretic models, and approaches based on experiments with animals for modeling crowd evacuation from a building. The paper compared and contrasted these approaches and discussed their associated advantages and disadvantages. The authors concluded that a variety of approaches should be combined to more accurately model crowd evacuation. Chen *et al.* [17] performed a study using agent-based simulation to model and analyze hurricane evacuation procedures in the Florida Keys. Taaffe *et al.* [18] described a simulation model for assessing hospital evacuation under emergency situations, such as a hurricane. They designed experiments based on resource utilization, such as number of staff and vehicles used in the model. Different scenarios were tested to identify the bottleneck of the described system.

It is important that all occupants should be able to evacuate to safety from large public buildings under fire conditions. In the paper by Shi *et al.* [19,20], a system simulation model was presented, in which a physical model and a mathematical model were both

included. On the basis of agent technology, a computer program was developed to simulate and analyze the egress progress in large public buildings through combining rule reasoning with numerical calculation, and some crowd pedestrian flow phenomenon. By coupling with the fire scenario simulated by CFD technology, the computer simulation program may represent the overall and dynamic process of occupants' evacuation under fire expansion, and the mutual relationship between occupants' safety and fire hazard. An indoor stadium which was used as a competition venue for the 2008 Beijing Olympic Games was studied.

Since the strategies and factors influencing evacuation differ greatly based on the size of the venue, much research has been conducted for both, small physical parameters and large-scale parameters such as geographical layouts. Simulating large area evacuation usually requires more parameters and data. The physical characteristics of a structure affect the success of an evacuation. It has been shown in different studies that building environment, involving exit position, exit width, obstacle distribution, slope of stairs, and so on, significantly affect the emergency egress time [19–21]. Also, according to Wong and Fong [22], the number of occupants, the ratio of floor space to the number of occupants, and the specific flow rate at the exit are significant factors of the risk to people during an evacuation.

Saadatseresht *et al.* [23] considered the traveling distance between a safe area and the point of evacuation to be an important parameter in building a multiobjective optimization model for constructing a city-wide evacuation plan. Pidd *et al.* [24] developed a decision support system that combines a geographical information system (GIS) with microsimulator tools. It can model the mitigation of the public in a certain area under emergency threats such as chemical leak. However, the system is computationally intensive and is not suitable for real-time simulation or scenario-based decision analysis.

There has also been much discussion focused on model speed, because the computational time of an emergency evacuation

planning model is a key factor of its functionality. Many of the models developed for planning emergency evacuations are of high computational complexity, which prohibits them from providing real-time decision support capability. Two examples of these systems are the multiobjective optimization model developed by Saadatseresht *et al.* [23], and the spatial decision support systems developed by Pidd [24] and de Silva and Eglese [25]. Microsimulators, which capture the detailed movement of individual entities, are usually computationally expensive, but these models allow integration of real-life factors. On the other hand, macrosimulators are inadequate for tracking detailed behavior of individual agents, but they are less computationally demanding than microsimulators [24]. Few models have been developed for real-time simulation. Papamichail and French [26] developed a real-time on-line decision support system (RODOS) that assists in the evaluation and ranking of alternative strategies in order to specify countermeasures. A coarse expert system (CES) was developed at the University of Manchester to cut down the large number of strategies that may arise in nuclear emergencies.

Bakuli and Smith [27] used state-dependent queueing network models incorporating the mean value analysis algorithm within Powell's derivative-free unconstrained optimization algorithm to design an emergency evacuation network. This method helps to specify design parameters for circulation space that would accommodate the requirement for both normal circulation and an emergency.

Chen *et al.* [28] developed a heuristic algorithm based on the Lagrangian relaxation for optimizing emergency sign locations with consideration of light-occlusion effects. On the basis of a cellular automata model, the evacuation efficiency of the optimized locations of emergency signs derived from the algorithm was verified. Through simulation to compare evacuation efficiency of the same supermarket with and without existing emergency signs, it showed that by enlarging the coverage of emergency signs, evacuation efficiency can be improved.

The article by Hobeika and Kim [29] described a software tool, MASSVAC 4.0, developed to model the evacuation of an area near a nuclear power plant. Although radiation exposure is a very rare event, the Nuclear Regulatory Commission requires detailed evacuation plans for all plants. The article described several generations of evacuation software designed to analyze, evaluate, and develop different evacuation strategies. The software combines a traffic-assignment module, a simulation module, and a user-interface module. The most recent addition to the software is a traffic-assignment method based on user equilibrium.

A crowd simulation system, MACES, was developed at the University of Pennsylvania that integrates a psychological model for emergency behaviors [30]. This crowd simulation system was capable of a high level way-finding that explores unknown environment to build knowledge of the surrounding areas for navigation. The model was capable of dealing with low level motion within each room, based on social forces. Communication and roles were also included to simulate information spread during emergencies. To expand the range of realistic human behaviors, a system called PMFserv were also included. The two systems were integrated to add validated agent behavior to crowd simulation.

Samuelson *et al.* [31] described real-time models that simulate mass egress of a stadium and a subway station. The models were built based on NetLogo, a simulation model platform. An identified problem with subway simulation was that adding too many choices of crowd behavior could push the model beyond what NetLogo can handle with acceptable execution times.

Luo *et al.* [32] developed a model that adopts an agent-based approach and employs a layered framework to reflect the natural pattern of a human-like decision making process, which generally involves a person's awareness of the situation and consequent changes on the internal attributes.

Chen and Zhan [33] used an agent-based technique to model traffic flows at the level of individual vehicles and investigated the collective behaviors of evacuating vehicles.

The problem with network flow models is that they cannot capture the behavior of individual vehicles. They compared the performance of simultaneous and staged evacuation strategies, but found that performance of the strategies depend on both road network structure and population density.

Shendarkar *et al.* [34] presented a novel VR (Virtual Reality)-trained BDI (belief, desire, intention) software agent used to construct crowd simulations for emergency response. The BDI framework allows modeling of human behavior with a high degree of fidelity. The proposed simulation has been developed using AnyLogic software to mimic crowd evacuation from an area under a terrorist bomb attack. The attributes that govern the BDI characteristics of the agent were studied by conducting human in-the-loop experiments in VR using the Cave Automatic Virtual Environment. To enhance the generality and interoperability of the crowd simulation modeling scheme, input data models have been developed to define environment attributes. Experiments were also conducted to demonstrate the effect of various parameters on key performance indicators such as crowd evacuation rate and densities. However, this model was not real-time.

Agent routing in E-SIM is computed using a two-level hierarchical path-finding approach based on the A* algorithm, a tree search algorithm that finds a path from a given initial node to a given goal node. It employs a heuristic estimate which ranks each node by an estimate of the best route that goes through that node. Each agent also has the ability to remember problems or obstructions that they encountered while attempting to exit the facility [36].

CHALLENGES

Evacuating large crowds of people under any circumstance is a challenge. Evacuation of large facilities during a disaster or an emergency further complicates the complex task because of the added elements of chaos, panic, the high density of the population, and the potential dependencies of supporting services. As terrorists move more toward

preying on soft targets such as airports, train stations, sport stadiums, and public theater districts, the potential for large government, commercial, residential, and sports facilities to become targets become a reality for which we must prepare. Further, such preparedness is necessary as we have seen the devastation resulting from inadequate planning and training for mass evacuations. The 2005 Hurricane Katerina killed at least 1836 people in the actual hurricane and in the subsequent floods, making it the deadliest US hurricane since the 1928 Okeechobee hurricane, with total property damage estimated at \$81 billion (2005 USD) [35], nearly triple the damage wrought by Hurricane Andrew in 1992.

Determining the most effective evacuation plan for a large public facility requires in-depth analysis of multiple interdependent and competing factors. Determining the best routes, foreseeing potential problems, addressing the chaos/panic factor, and orchestrating the evacuation are all critical aspects that should be evaluated in a well-developed disaster management plan. The success of the evacuation of 80,000 at the stadium Santiago Bernabeu in Madrid, Spain within seven min sheds some light on the potential to save many lives through careful planning and proper evacuation responses. Emergency responders and coordinators must be equipped with such knowledge so as to protect the regional population during critical incidents [1].

In the academic and research frontier, challenges remain in the trade-offs between the realism of the models that can accommodate the multifaceted complexity of the evacuation process versus their computational intractability. Researchers have to continue to push the frontier of computational strategies that can solve large-scale evacuation instances where they allow for scenario-based analysis and development of useful and practical evacuation guidance for maximizing evacuation success.

INTRODUCTION

This survey article addresses the solution of the mixed-integer program (MIP)

$$z = \min_{x \in X} \left\{ c^\top x : X = \left\{ Ax \geq b, x \in \mathbb{Z}_+^p \times \mathbb{R}_+^{n-p} \right\} \right\}, \quad (1)$$

by means of adding valid linear inequalities (also referred to as *cutting planes* or *cuts*) to its *linear programming* (LP) relaxation. The LP relaxation of Equation 1 is given by,

$$z_\ell = \min_{x \in X_\ell} \left\{ c^\top x : X_\ell = \left\{ Ax \geq b, x \in \mathbb{R}_+^n \right\} \right\}. \quad (2)$$

Here $c \in \mathbb{Q}^n$, $A \in \mathbb{Q}^{m \times n}$, and $b \in \mathbb{Q}^m$. A *valid inequality* for MIP Equation 1 is an inequality $\pi^\top x \geq \pi_0$, where $(\pi, \pi_0) \in \mathbb{R}^{n+1}$ such that $X \subseteq \{x : \pi^\top x \geq \pi_0\}$. We refer the reader to Marchand *et al.* [1], Cornuéjols [2], and other articles in the encyclopedia for an introduction to valid inequalities for structured and unstructured MIPs.

A fundamental result in MIP (see, e.g., Theorems 6.2 and 6.3 Chapter I.4 in Nemhauser and Wolsey [3]) states that solving problem 1 is equivalent to solving the LP:

$$z = \min \left\{ c^\top x : x \in \text{clconv}(X) \right\},$$

where $\text{clconv}(X)$ denotes the closure of the convex hull of X . Moreover, it can be shown that $\text{clconv}(X)$ is a polyhedron. However, constructing a linear description of $\text{clconv}(X)$ *a priori* is a difficult task and instead, the cutting-plane approach iteratively constructs tighter linear approximations of $\text{clconv}(X)$. Given a family of valid inequalities $\Pi := \{(\pi, \pi_0) \in \mathbb{R}^{n+1} : X \subseteq \{x : \pi^\top x \geq \pi_0\}\}$, a pure *cutting-plane* method for solving MIPs attempts to find a valid inequality (π, π_0) for X that cuts off the fractional solution $\bar{x}$ of the LP relaxation, that is, $\pi^\top \bar{x} < \pi_0$. The problem of finding a violated inequality is referred to as *separation*. A generic cutting-plane algorithm for a given family of valid inequalities Π for X is given in Algorithm 1.

The algorithm begins with using the linear relaxation X_ℓ of X as an initial approximation of $\text{clconv}(X)$. In an iteration k of the algorithm, an LP corresponding to the k th approximation, X_ℓ^k is solved and the solution vector x^k is obtained. If x^k satisfies the mixed-integer requirement, then, because x^k is an optimal solution to a relaxation of Equation 1, and feasible in X , it is also optimal. If this is not the case, then the algorithm proceeds by choosing a valid inequality $\pi^\top x \geq \pi_0$ that is violated by the current solution with $\pi^\top x^k < \pi_0$ (assuming that it exists in the given family), and the subsequent relaxation X_ℓ^{k+1} is formed by adding the valid inequality to X_ℓ^k . These steps are repeated until a mixed-integer feasible solution is found or until no valid inequalities to separate x^k can be found.

Algorithm 1 A Generic Cutting-Plane Algorithm for MIP

- 1: *Initialization.* $k \leftarrow 0, X_\ell^k \leftarrow X_\ell$.
 - 2: **while** $x^k := \arg \min_{x \in X_\ell^k} c^\top x \notin \mathbb{Z}_+^p \times \mathbb{R}_+^{n-p}$
 - 3: *Separation.* Find an inequality $(\pi, \pi_0) \in \Pi$ such that $\pi^\top x^k < \pi_0$. If none exists, goto 6
 - 4: $X_\ell^{k+1} \leftarrow X_\ell^k \cap \{x : \pi^\top x \geq \pi_0\}$.
 - 5: $k \leftarrow k + 1$.
 - 6: **end while**
-

A natural question that arises regarding a cutting-plane algorithm is whether it converges to an optimal solution of MIP (if it exists) in finitely many steps. This question is important not only in the context of MIP but also for designing algorithms for stochastic MIPs. In this article, we survey cutting-plane algorithms for subclasses of MIPs and discuss the key results needed to show their convergence for different classes of MIPs. We also give examples to show nonconvergence when applied to other classes of problems. We begin with a discussion of the Gomory cutting-plane method and its convergence for pure integer programs.

ALGORITHMS USING LEXICOGRAPHY AND ROUNDING

First, we discuss the Gomory cutting-plane algorithm [4], which is one of the first cutting-plane algorithms developed to solve pure integer programming problems ($p = n$ in Eq. 1). Gomory cuts and extensions are discussed elsewhere in this encyclopedia (please refer to the encyclopedia article by R. Fukasawa).

We make the following assumptions:

- The data of the MIP are integral, that is, $c \in \mathbb{Z}^n, A \in \mathbb{Z}^{m \times n}, b \in \mathbb{Z}^m$. This assumption is without the loss of generality because the original rational coefficients can be appropriately scaled to obtain an equivalent representation of X using integer coefficients.
- The problem is stated equivalently by minimizing the variable x_0 and adding the constraint $x_0 = c^\top x$ to the constraint set.

For the sake of completeness, we derive the Gomory fractional cut in this article. Let $\bar{x}$ be the optimal solution to the LP relaxation (Eq. 2), let $\mathcal{B}$ and $\mathcal{N}$ denote the index set of basic and nonbasic variables associated with this optimal solution, respectively, and let B and N denote the columns of basic and nonbasic variables, respectively. If $\bar{x} \in \mathbb{Z}_+^n$, then we have found an optimal solution to the MIP. Otherwise, we choose a row of the

simplex tableau corresponding to a variable $i \in \mathcal{B}$, such that $\bar{x}_{\mathcal{B}(i)} \notin \mathbb{Z}$:

$$x_{\mathcal{B}(i)} + \sum_{j \in \mathcal{N}} \bar{a}_{ij} x_j = \bar{b}_i, \quad (3)$$

where $\bar{a}_{ij}$ is a component of the matrix $B^{-1}N$, $\mathcal{B}(i)$ is the i th basic variable and $\bar{b}_i := \bar{x}_{\mathcal{B}(i)}$. Because $x_j \geq 0$ for all j , we can write

$$x_{\mathcal{B}(i)} + \sum_{j \in \mathcal{N}} \lceil \bar{a}_{ij} \rceil x_j \geq \bar{b}_i.$$

Furthermore, because $x_j \in \mathbb{Z}$ for all j , we have,

$$x_{\mathcal{B}(i)} + \sum_{j \in \mathcal{N}} \lceil \bar{a}_{ij} \rceil x_j \geq \lceil \bar{b}_i \rceil. \quad (4)$$

Subtracting Equation 3 from Equation 4, we get the Gomory fractional cut as

$$\sum_{j \in \mathcal{N}} \phi(\bar{a}_{ij}) x_j \geq \phi(\bar{b}_i), \quad (5)$$

where $\phi(\beta) := \lceil \beta \rceil - \beta$. Note that the current basis and solution is cut off by Equation 5. An iteration of Gomory's cutting-plane algorithm involves solving an LP associated with the current iteration. If the solution is fractional, then a cut in the form (5) is generated, which is guaranteed to cut off this fractional solution.

The proof of convergence of Gomory's fractional cutting-plane algorithm relies on the lexicographic dual simplex method [3, 7, 8] (see the article by M. Banciu in the encyclopedia for a description of the lexicographic dual simplex method). Given two vectors $v^1, v^2 \in \mathbb{R}^n$, v^1 is said to be *lexicographically larger* than v^2 , denoted as $v^1 \succ v^2$, if there exists a k such that $v_k^1 > v_k^2$ and $v_j^1 = v_j^2$ for all $j = 1, \dots, k-1$. We say that v^1 is lexicographically larger than or equal to v^2 , denoted by $v^1 \succeq v^2$, if either $v^1 \succ v^2$ or $v^1 = v^2$. In the lexicographic dual simplex method, one begins with and maintains simplex tableaus that are lexicographically dual feasible, that is, tableaus that are dual feasible and have all the nonbasic columns lexicographically smaller than the zero vector. This is accomplished using a

lexicographic pivoting rule. This approach ensures that the simplex method does not cycle, and furthermore, guarantees that the lexicographically smallest optimal solution to the LP, if it exists, is found in *finitely many steps*.

In line 3 of Algorithm 1, when one uses the Gomory fractional cutting-plane method for pure integer programs, one solves the k th relaxation using the lexicographical dual simplex method. Because $X_\ell^{k+1} \subset X_\ell^k$ for each iteration k with a fractional solution x^k , we obtain a sequence of lexicographically increasing solutions $\{x^t\}_{t=0}^k$ during the execution of the cutting-plane procedure. What remains to be seen is whether this sequence converges to an integer solution in finitely many steps.

It is a well-known fact that if $\hat{x}$ is an extreme point of $\text{conv}(X)$, then there exists $M < \infty$ such that $\hat{x}_j \leq M$ with $M \in \mathbb{Z}$ for $j = 1, \dots, n$ (see Nemhauser and Wolsey [3], Theorem 4.1 in Chapter I.5). That is, the extreme point components of the convex hull of an integer set within a polyhedron are bounded. Moreover, the bound depends only on the problem data. Let $\beta^- := \min(\beta, 0)$ and $\beta^+ := \max(0, \beta)$. From the preceding fact, it follows that if $x \in X$, then

$$\begin{aligned} \left(\sum_{j=1}^n c_j^+ M, M, \dots, M \right)^\top &\succeq x \\ &\succeq \left(\sum_{j=1}^n c_j^- M, 0, \dots, 0 \right)^\top. \end{aligned} \quad (6)$$

The following result establishes the fact that Gomory cuts, when used with the lexicographic dual simplex method and when cuts are chosen from the smallest index variable that is fractional in the solution, have a certain “rounding” property.

Proposition 1 [8]. *Let x^t denote the lexicographically smallest optimal solution to $\min_{x \in X_\ell^t} c^\top x$, $t = k-1, k$, where the updated approximation X_ℓ^k is formed by adding to X_ℓ^{k-1} a Gomory cut (Eq. 5) corresponding to the smallest index source row of the fractional solution x^{k-1} . Let i_k denote the index of the*

variable used to form the Gomory cut and define

$$\alpha^k := \left(x_0^{k-1}, x_1^{k-1}, \dots, x_{i_k-1}^{k-1}, \lceil x_{i_k}^{k-1} \rceil, 0, \dots, 0 \right)^\top. \quad (7)$$

Then,

$$x^k \succeq \alpha^k \succeq x^{k-1}.$$

It is important to note that the fractional variable with the smallest index is chosen for cut generation. Finite convergence of the Gomory cutting-plane method follows because from Proposition 1, we obtain a sequence of lexicographically increasing vectors at each iteration, and there are only finitely many integer vectors that satisfy Equation 6.

Theorem 1 [3, 8]. *Suppose that at every iteration of the Gomory cutting-plane method, the cut is formed by choosing the smallest index source row of the fractional solution, and the lexicographic dual simplex method is used to optimize the updated problems. Then, the cutting-plane method finds an optimal solution or concludes that the problem is infeasible in finitely many steps.*

Note that as long as the Gomory cut from the smallest index source row is present, lexicography allows other valid inequalities to be added to the subsequent approximation X_ℓ^{k+1} of the Gomory cutting-plane method without losing finite convergence. For example, one can add as many Gomory cuts as there are fractional variables in the solution to the current approximation. This approach of adding cuts corresponding to all fractional variables in the linear relaxation is referred to as adding a *round of cuts*.

For the Gomory cutting-plane algorithm, the key elements needed to show convergence are lexicography and the choice of the source row for cut generation. The nature of convergence can be interpreted as pruning nodes in a lexicographic enumeration tree (cf. [3]). In this tree, the nodes at level j correspond to an index of a variable. For example, the root node corresponds to the objective function

variable x_0 and there are as many branches as there are possible values of the variable. All possible integer vectors satisfying Equation 6 are arranged in a lexicographic order. In an iteration k , any vector in the tree that is strictly lexicographically smaller than α^k can be thought of as pruned. Thus, by means of this tree, lexicography implicitly provides a “memory” of vectors pruned. We shall see that the concept of “memory” is a recurrent theme in the convergence proofs of various cutting-plane algorithms throughout this article.

Lexicography has also been used in other finitely convergent cutting-plane algorithms. Neto [9] proposes an iterative lexicographic optimization method for the solution of MIPs. The author shows that under the assumptions that the optimal objective function is integral and bounded, and the integer variables are bounded, the algorithm converges in finitely many iterations to the lexicographically smallest optimal solution. Unlike Gomory’s cutting-plane method, the cutting planes in this algorithm are not derived from the simplex tableau of the LP relaxation. They are not necessarily valid for the convex hull of solutions to the MIP, but they cut off a fractional LP solution, while ensuring that any lexicographically smaller integer feasible solution is not cut off. This algorithm is a generalization of the algorithm in [10], which gives a finite cutting-plane algorithm for mixed-binary problems with integral optimal objective function values. Other finitely convergent algorithms for pure integer programs are proposed in [11, 12, 13].

Gomory also proposed the Gomory mixed integer (GMI) cuts [14] for general MIP problems. When the objective function value is known to be integer, the proof for the pure integer case can be adapted to show finite convergence for the mixed-integer case. However, if the objective function value is no longer required to be integer, a cutting-plane algorithm based on GMI cuts may not converge. The following example [15] (see also Padberg [16]) is an instance on which GMI

cuts do not converge.

$$\begin{aligned} \min & -x_3 \\ & -x_1 - x_2 - x_3 \geq -2 \\ & x_1 - x_3 \geq 0 \\ & x_2 - x_3 \geq 0 \\ & x_1, x_2 \in \mathbb{Z}_+, x_3 \in \mathbb{R}_+. \end{aligned} \tag{8}$$

One can easily observe that $x_3 = 0$ in an optimal solution to this example. When one does not consider the objective function row corresponding to x_3 for cut generation, Padberg [16] shows that the optimal solution at the k th iteration of the GMI cutting-plane method (when a round of cuts is added in every iteration) is $x_1^k = x_2^k = (2k + 2)/(2k + 3)$, and $x_3^k = 2/(2k + 3)$. Thus, for any iteration k one has $x_3 > 0$ and only obtains an optimal solution as $k \rightarrow \infty$.

Although Gomory fractional and mixed-integer cuts were developed in the late 1950s and early 1960s, they were not widely used until the late 1990s. Balas *et al.* [17] demonstrated the computational effectiveness of Gomory cuts when used within a branch-and-cut scheme. More recently, Zanette *et al.* [18] showed that the performance of a pure Gomory fractional cutting-plane method is far superior when the lexicographic dual simplex method is used instead of the regular dual simplex. In their implementation, instead of using the lexicographic pivoting rule in the dual simplex, they use a post-processing scheme to obtain the lexicographically smallest solution. Other computational enhancements are reported in [19].

ALGORITHMS USING SEQUENTIAL CONVEXIFICATION

Lift-and-Project Cutting-Plane Algorithm

In this section, we discuss the lift-and-project cutting-plane algorithm [5] for mixed binary programs, that is, the mixed-integer restrictions in Equation 1 are $x \in \{0, 1\}^p \times \mathbb{R}_+^{n-p}$. The lift-and-project algorithm has its roots in disjunctive programming. Disjunctive programming was introduced by

Balas [20] and refers to optimization over union of polyhedra. Disjunctions arise naturally in integer programming. For example, a binary restriction on a variable $x_j \in \{0, 1\}$ can be represented as a disjunction $(x_j = 0) \vee (x_j = 1)$, where $\vee$ denotes the logical “or” operator. Similarly, an integer variable $x_j \in [0, U_j] := \{0, 1, \dots, U_j\}$ can be represented using the disjunction $(x_j = 0) \vee (x_j = 1) \vee \dots \vee (x_j = U_j)$. A variety of disjunctions can be used to generate cuts for an MIP. For example, when the LP relaxation of an MIP yields a solution $\bar{x}$ with $\bar{x}_j$ fractional for $j \in \{1, \dots, p\}$, a disjunction of the type $(X_\ell \cap \{x_j \leq \lfloor \bar{x}_j \rfloor\}) \vee (X_\ell \cap \{x_j \geq \lceil \bar{x}_j \rceil\})$ can be written to produce a cut that separates this point from $\text{clconv}(X)$. When the disjunction used for cut generation contains only two terms of the type mentioned earlier, we refer to such cuts as elementary disjunctive cuts. More general two-term disjunctions (e.g. *split disjunctions* [21]), disjunctions with more than two terms (multiterm disjunctions), and so forth can be considered to generate violated inequalities. We refer the reader to the articles in this encyclopedia by L. Liberti, Q. Louveaux and K. Andersen, and the references therein for further details.

The lift-and-project algorithm relies on a sequential convexification property of mixed binary programs. Mixed binary programs inherit this property from a more general class of problems called *facial disjunctive programs* (cf. [22]). Given a general MIP (Eq. 1), the convexification with respect to a variable $x_j, j \in \{1, \dots, p\}$ and a polyhedron Y is defined as:

$$P_j(Y) := \text{clconv}(Y \cap \{x : x_j \in \mathbb{Z}\}).$$

Let $i_1, \dots, i_t$, where $i_j \in \{1, \dots, p\}, j = 1, \dots, t$ be variable indices. For $t \geq 2$ define

$$P_{i_t, \dots, i_1}(X_\ell) := P_{i_t}(P_{i_{t-1}}(\dots(P_{i_1}(X_\ell))\dots)),$$

that is, first, the mixed-integer set defined by imposing integrality of x_{i_1} to X_ℓ is convexified. This results in the set $P_{i_1}(X_\ell)$. Then, the set defined by imposing integrality of x_{i_2} to $P_{i_1}(X_\ell)$ is convexified, and so forth. Imposing

integrality variable-by-variable and taking the closure of the convex hull at each step is referred to as *sequential convexification* in the sequence defined by the permutation $i_1, \dots, i_p$.

For mixed-binary programs, when the sets are convexified with respect to the binary variables sequentially in the manner described earlier, Balas [20] showed that after p steps, one obtains the closure of the convex hull of X , that is, $P_{i_p, \dots, i_1}(X_\ell) = \text{clconv}(X)$. Balas [20] also gave an example showing that for general MIPs (with $x \in \mathbb{Z}_+^p \times \mathbb{R}_+^{n-p}$), sequential convexification may fail to yield $\text{clconv}(X)$. Note that general MIPs are not a subclass of facial disjunctive programs.

Theorem 2 [5, 20]. *For mixed binary programs*

$$P_{i_p, \dots, i_1}(X_\ell) = \text{clconv}(X).$$

Sherali and Adams [23, 24] give an alternative finite characterization of the convex hull of the binary and mixed-binary integer programs based on the reformulation-linearization technique (RLT). We refer the reader to the encyclopedia article by H. D. Sherali for further details. See also [25] for another finite construction of the convex hull.

Assume that the constraints $Ax \geq b$ in the mixed-binary program include the constraints $x \leq 1$. In the lift-and-project cutting-plane method, cut generation is a two-step process. The first step is a lifting step, which involves representing the convex hull of the disjunctive program as an LP in a higher dimensional space (of dimension larger than n). We shall consider the constructions in [5]. If the solution to the linear relaxation is fractional, with x_j fractional, then one first constructs the nonlinear system

$$(1 - x_j)(Ax - b) \geq 0$$

$$x_j(Ax - b) \geq 0.$$

This system is linearized by setting $x_i x_j =: z_i, i \neq j$ and $x_i^2 = x_i$ (the latter identity holds because x_j is binary). The new linear system

has additional variables; let its feasible set be denoted by $M_j(X_\ell)$. Alternatively, one can write a disjunction

$$D_j := (X_\ell \cap \{x_j = 0\}) \vee (X_\ell \cap \{x_j = 1\}). \quad (9)$$

Consider the LP,

$$\begin{aligned} & \min c^\top x \\ & Ay^1 - by_0^1 \geq 0 \\ & Ay^2 - by_0^2 \geq 0 \\ & -y_j^1 = 0 \\ & y_j^2 - y_0^2 = 0 \\ & y_0^1 + y_0^2 = 1 \\ & x = y^1 = y^2. \\ & x, y^1, y^2 \geq 0, y_0^1, y_0^2 \geq 0, \end{aligned}$$

and let $K_j(X_\ell)$ denote the feasible region of this LP.

The second step of the lift-and-project algorithm is to project the higher dimensional LP onto the space of the original variables. Balas *et al.* [5] show that the projection of $M_j(X_\ell)$ (equivalently, the projection of $K_j(X_\ell)$) onto the space of x variables yields $P_j(X_\ell)$. Balas *et al.* [5] show that valid inequalities for $P_j(X_\ell)$ correspond to feasible points of projection cone of $M_j(X_\ell)$. If X_ℓ is full dimensional, the facets of $P_j(X_\ell)$ correspond to the extreme rays of the projection cone of $M_j(X_\ell)$. These results are specialized versions of the more general result on the compact representation of the closure of the convex hull of a disjunctive program in a higher dimensional space [22]. In order to produce violated lift-and-project cuts for a fractional solution to the linear relaxation, one writes the so-called cut generation linear program (CGLP), which is formulated by writing the projection cone of $M_j(X_\ell)$ (or $K_j(X_\ell)$) and adding a normalization constraint that truncates the cone (see also [26]). In addition, one adds an objective function, for example, an objective function that maximizes the violation of the cut.

In a cutting-plane algorithm that employs lift-and-project cuts for mixed-binary programs, one can always generate a violated

inequality for a fractional solution by forming a disjunction. However, as shown in an example in Sen and Serali [27], a naive implementation of the lift-and-project cutting-plane algorithm may not be finitely convergent. They show that appropriate memory needs to be maintained to guarantee finite convergence. The main idea behind the convergence proof of the lift-and-project algorithm is to carefully select the fractional variables and polyhedra for generating cuts that lead to sequential convexification of the linear relaxation with respect to the binary variables. To this end, let a j -cut be a valid inequality for $P_j(\cdot)$ obtained by solving a CGLP with an appropriate normalization. Also let S_i^k be the polyhedron defined by the inequalities $Ax \geq b$ and all j -cuts for $j = 1, \dots, i$ at iteration k , and let S_0^k denote the linear relaxation X_ℓ . In line 3 of Algorithm 1, to generate a cut, one chooses the *largest index* $j \in \{1, \dots, p\}$ such that x_j is fractional, and generates an inequality for $P_j(S_{j-1}^k)$ using the CGLP with an appropriate normalization constraint. One can show that the cut generated for $P_j(S_{j-1}^k)$ cuts off the fractional solution x^k . To show finite convergence, observe that because the projection cone of $M_1(S_0^k) = M_1(X_\ell)$ has finitely many extreme points, this set is convexified with respect to x_1 after the addition of finitely many 1-cuts. By induction, one can show that the number of j -cuts generated is finite for all $j = 1, \dots, p$. Thus, in the worst case, we will have constructed $\text{clconv}(X)$ in finitely many steps, at which point an optimal solution (if it exists) is found. Let m_j be the iteration index when the last i -cut was generated for $i = 1, \dots, j$. Note that $S_j^k = S_j^{m_j}$ in all iterations $k \geq m_j$. Therefore, the iteration index m_j provides the memory of inequalities defining S_j^k for each j , and it plays an important role in the convergence proof. We refer the reader to Sen and Serali [27] for a related proof of convergence and [28, 29] for an alternative finitely convergent implementation of a pure cutting-plane algorithm for facial disjunctive programs.

Theorem 3 [5]. *Suppose at each iteration k , the lift-and-project cutting-plane algorithm is implemented by selecting*

the largest index j that is fractional and generating a cut corresponding to an extreme point of CGLP (with appropriate normalization) formed using the polyhedron S_{j-1}^k . Then, the cutting-plane method finds an optimal solution or concludes that the problem is infeasible in finitely many steps.

The first computational results incorporating lift-and-project cuts within a branch-and-cut algorithm are reported in [30]. We refer the reader to the encyclopedia article by Q. Louveaux for a survey of recent computational developments.

Cutting-Plane-Tree Algorithm

As discussed earlier, a variable-by-variable sequential convexification may not yield the convex hull of feasible solutions for general MIPs. In fact, Owen and Mehrotra [31] give the following example, showing that when the lift-and-project cutting-plane algorithm is applied to the mixed-integer case, one may not converge to an optimal solution even in the limit.

$$\begin{aligned} \min & -x_1 - x_2 \\ \text{s.t.} & 8x_1 + 12x_2 \leq 27 \\ & 8x_1 + 3x_2 \leq 18 \\ & 0 \leq x_1, x_2 \leq 3 \\ & x \in \mathbb{Z}_+^2. \end{aligned}$$

It can be easily verified that the convex hull of the feasible set of MIP given above is $\{x \in \mathbb{R}_+^2 : x_1 + x_2 \leq 2\}$. However, an application of the lift-and-project algorithm using elementary (two-term) disjunctions of the type $(X_\ell \cap \{x_j \leq \lfloor \bar{x}_j \rfloor\}) \vee (X_\ell \cap \{x_j \geq \lceil \bar{x}_j \rceil\})$ yields in the limit the set $\{x \in \mathbb{R}_+^2 : x_1 + x_2 \leq 2.25\}$.

In a recent article, Chen *et al.* [6] propose the cutting-plane-tree (CPT) algorithm, which uses cuts derived from multiterm disjunctions. The multiterm disjunctions partition the feasible region into a finite collection of intervals for each variable, the union of which gives contains the feasible domain. Iteratively finer partitions are obtained over the course of the algorithm.

We first review a convexification result for general MIP proposed by Chen *et al.* [6]. Assume that each integer variable is bounded and can take integer values in the interval $[0, U_j]$. Let each interval be further divided into subintervals

$$[L_{1j} := 0, U_{1j}], [L_{2j}, U_{2j}], \dots, [L_{t_{jj}}, U_{t_{jj}} := U_j],$$

where $L_{\kappa_{jj}}, U_{\kappa_{jj}} \in \mathbb{Z}_+$, $L_{\kappa_{jj}} \leq U_{\kappa_{jj}}$ and $\kappa_j \in \{1, \dots, t_j\}$, $j = 1, \dots, p$ with $L_{\kappa_{j+1}j} - U_{\kappa_{jj}} \leq 1$ for $\kappa_j \in 1, \dots, t_j - 1$ so that the subintervals span all integers in $[0, U_j]$. Given such partition $\mathcal{P}$, the collection of all p -tuples of the form $\kappa = (\kappa_1, \kappa_2, \dots, \kappa_p)$ is denoted by $K(\mathcal{P})$. A unit partition $\mathcal{P}^*$ is a partition where $U_{\kappa_{jj}} - L_{\kappa_{jj}} \leq 1$ for all $\kappa_j \in \{1, \dots, t_j\}$, $j = 1, \dots, p$. For $\kappa \in K(\mathcal{P}^*)$, $j \in \{1, \dots, p\}$, and a polyhedron $\bar{X}$, we define the following sets:

$$\begin{aligned} \mathcal{P}^-(\kappa, j, \bar{X}) &:= \left\{ x \in \bar{X} : L_{\kappa_i i} \leq x_i \leq U_{\kappa_i i}, \right. \\ &\quad \left. i = 1, \dots, p; x_j \leq L_{\kappa_{jj}} \right\} \end{aligned}$$

and,

$$\begin{aligned} \mathcal{P}^+(\kappa, j, \bar{X}) &:= \left\{ x \in \bar{X} : L_{\kappa_i i} \leq x_i \leq U_{\kappa_i i}, \right. \\ &\quad \left. i = 1, \dots, p; x_j \geq U_{\kappa_{jj}} \right\}. \end{aligned}$$

In addition, we define $\mathcal{H}_j^\kappa(\bar{X}) := \text{clconv}(\mathcal{P}^-(\kappa, j, \bar{X}) \cup \mathcal{P}^+(\kappa, j, \bar{X}))$. The following theorem gives a sequential convexification result for a general MIP with respect to a unit partition $\mathcal{P}^*$.

Theorem 4 [6]. *Assume that the set X as defined in (1) is nonempty and has bounded integer variables. Then for any unit partition $\mathcal{P}^*$,*

$$\begin{aligned} \text{clconv}(X) &= \text{clconv}\left\{ \bigcup_{\kappa \in K(\mathcal{P}^*)} \right. \\ &\quad \left. [\mathcal{H}_p^\kappa(\mathcal{H}_{p-1}^\kappa(\dots(\mathcal{H}_1^\kappa(X_\ell))\dots)) \setminus \emptyset] \right\}. \end{aligned}$$

Adams and Sherali [32] propose an alternative finite convex hull characterization for general MIP based on Lagrange interpolation polynomials. Similar to the case with mixed-binary programs described in the section

titled “Lift-and-Project Cutting-Plane Algorithm”, the existence of a finite convex hull representation suggests the existence of a finite pure cutting-plane algorithm. However, care must be taken in the design of the algorithm to guarantee convergence. Next, we describe such an algorithm, referred to as the *CPT algorithm* [6].

In the CPT $\mathcal{T}$, there is a single root node o . For each node $\sigma \in \mathcal{T}$, an integer $v_\sigma \in \{1, 2, \dots, n_1\}$ stores the index of the integer variable that is split, an integer q_σ stores the (lower) level of the splitting. Let l_σ , r_σ , and p_σ denote the left child, right child, and parent nodes of node σ , respectively. Let $S(\sigma)$ be all nodes on the subtree rooted at node σ (not including node σ and the leaf nodes). Let $\mathcal{N}(\sigma)$ be the collection of the nodes on the path from the root node to node σ (not including the root node), $\mathcal{N}^-(\sigma)$ be the collection of nodes in $\mathcal{N}(\sigma)$ that were formed as the left child node of its parent, and $\mathcal{N}^+(\sigma)$ be the collection of nodes in $\mathcal{N}(\sigma)$ that were formed as the right child node of its parent. Given $\sigma \in \mathcal{T}$ define

$$\begin{aligned} \mathcal{C}_\sigma &= \{x | x_j \in [0, U_j], x_{v_{ps}} \leq q_{ps}, \forall s \in \mathcal{N}^-(\sigma), \\ x_{v_{ps}} &\geq q_{ps} + 1, \forall s \in \mathcal{N}^+(\sigma)\} \end{aligned}$$

We let m_σ store an iteration index, which keeps track of the cutting planes that will be used to generate a disjunctive cut when this node is revisited. In other words, m_σ determines the set X^{m_σ} to be used in CGLP [20, 26]. The set X^{m_σ} corresponds to X_ℓ together with the first $m_\sigma - 1$ cuts added to it. If $X^{m_\sigma} \cap \mathcal{C}_{l_\sigma} = \emptyset$ ($X^{m_\sigma} \cap \mathcal{C}_{r_\sigma} = \emptyset$), we say that the left (right) child node of σ is “fathomed”, that is, $l_\sigma = \text{null}$ ($r_\sigma = \text{null}$).

At iteration k of the CPT algorithm, if the current extreme point solution to $\min_{x \in X_\ell^k} c^T x$, given by x^k is integral, then we have found an optimal solution to the MIP. Otherwise, we search the CPT to find the last node σ on the path from the root node such that $x^k \in \mathcal{C}_\sigma$. There are two cases. Case (1) σ is a leaf node ($\sigma \in \mathcal{L}_k$, where $\mathcal{L}_k$ is the set of leaf nodes of the CPT at iteration k) and Case (2) σ is not a leaf node ($\sigma \notin \mathcal{L}_k$, $x^k \in \mathcal{C}_\sigma$, $x^k \notin \mathcal{C}_{l_\sigma}$, and $x^k \notin \mathcal{C}_{r_\sigma}$). In Case (1), we choose a fractional variable

$x_j, j = 1, \dots, n_1$ with the smallest index, and let the split variable be $v_\sigma = j$. We create two new nodes: left (l_σ) and right (r_σ) children of σ at the split level $q_\sigma = \lfloor x_j^k \rfloor$. We let $\mathcal{C}_{l_\sigma} = \{x \in \mathcal{C}_\sigma | x_j \leq \lfloor x_j^k \rfloor\}$ and $\mathcal{C}_{r_\sigma} = \{x \in \mathcal{C}_\sigma | x_j \geq \lceil x_j^k \rceil\}$. In this case, we also let $m_\sigma = k$, as this is the first time the tree search for a fractional solution stops at node σ . Let $\mathcal{L}_{k+1} \leftarrow (\mathcal{L}_k \cup \{l_\sigma, r_\sigma\}) \setminus \{\sigma\}$. In Case (2), the CPT and m_σ are unchanged, that is, $\mathcal{L}_{k+1} \leftarrow \mathcal{L}_k$. However, in this case, we update $m_t = k$ for all successors of σ , $t \in S(\sigma)$. We generate a valid inequality for the set $\text{clconv}\{\cup_{t \in \mathcal{L}_{k+1}} (X^{m_\sigma} \cap \mathcal{C}_t)\}$ that cuts off x^k (from an extreme point of the associated CGLP). The new inequality is included along with those defining X^k , and the resulting set is denoted X^{k+1} . This process continues until an optimal solution to the MIP is obtained.

Theorem 5 [6]. *Assume that the set X is nonempty and has bounded integer variables. Then, the CPT algorithm converges to an optimal solution of the MIP in finitely many iterations.*

The convergence proof relies on the tree data structure and the iteration index m_σ that serves as memory for storing the subset of cuts generated until that iteration of the algorithm. A careful reader will recognize the similarity between the memory index m_j in the section titled “Lift-and-Project Cutting-Plane Algorithm” with the memory index m_σ introduced in this section.

Table 1 shows the first three iterations of the execution of the CPT algorithm on the example of Owen and Mehrotra [31] that was presented at the beginning of this section. In this table, k , x^k , σ , and m_σ denote the iteration number, solution of the relaxation, the node, and the memory parameter, respectively. The sets $\mathcal{Q}_i$ in an iteration represent a subset of $[0, 3] \times [0, 3]$ in which the current solution can fall. We begin the algorithm by solving the linear relaxation corresponding to the root node $\sigma = 1$ (setting $m_1 = 1$) and we obtain a fractional solution (15/8, 1). We create two child nodes for 1, namely 2 and 3 representing $x_1 \leq 1$ and $x_1 \geq 2$, respectively. We then generate a disjunctive cut using the CGLP corresponding to the disjunction

Table 1. First Three Iterations of the CPT Algorithm on Owen and Mehrotra's [31] example

k	x^k	σ	m_σ	$\mathcal{Q}_{k+1}$			Cut
1	(15/8, 1)	1	1	$Q_1 = [0, 1] \times [0, 3]$	$Q_2 = [2, 3] \times [0, 3]$		$11/12x_1 + x_2 \leq 5/2$
2	(2, 2/3)	3	2	$Q_1 = [0, 1] \times [0, 3]$	$Q_2 = [2, 3] \times [0, 0]$		$x_1 + 15/19x_2 \leq 9/4$
3	(1, 19/12)	2	3	$Q_1 = [2, 3] \times [0, 0]$	$Q_2 = [0, 1] \times [0, 1]$	$Q_3 = [0, 1] \times [2, 3]$	$x_1 + 15/16x_2 \leq 9/4$

defined by Q_1 and Q_2 on X_ℓ , add it to the linear relaxation and re-solve the problem to get $x^2 = (2, 2/3)$. As x^2 satisfies the bounds specified by node 3, and node 3 is a leaf node, we set $m_3 = 2$ and create two child nodes for node 3. As the set $X_\ell \cap \{x : 2 \leq x_1 \leq 3, 1 \leq x_2 \leq 3\}$ corresponding to the right child of 3 is infeasible, we remove it from further consideration. The CGLP in iteration 2 is constructed using X_ℓ , cut 1 (as $m_3 = 2$) and the disjunctions are defined by $Q_i, i = 1, 2$ and a disjunctive cut is generated. In the third iteration, on solving the updated relaxation, we get another fractional solution (1, 19/12), which falls at node 2, which is a leaf node. Therefore, we set $m_2 = 3$ and create two child nodes for node 2. It turns out that the right node of node 2 is infeasible; therefore, we discard it from further consideration and we are left with the sets $Q_i, i = 1, \dots, 3$. The algorithm proceeds in this manner and generates the cut $x_1 + x_2 \leq 2$ in the sixth iteration (see [6]). In the subsequent solution of the linear relaxation, we find an optimal integer solution and the algorithm terminates. Note that while the convex hull was generated at termination in this example, this generally need not be the case for the algorithm to terminate.

Computational results with a branch-and-cut algorithm based on cuts from the CPT are presented in [33]. Jörg [34] proposes another finitely convergent pure cutting-plane algorithm for general MIP using multiterm disjunctions in conjunction with Gomory cuts. An iteration of this approach involves the identification of all alternative optimal solutions of a related LP and the enumeration of all extreme rays of a polyhedral projection cone.

CONCLUSIONS

In this article, we survey different pure cutting-plane algorithms and the key results needed to show their convergence. Throughout, we emphasize the important role that memory plays in the convergence proofs. Various studies indicate that pure cutting-plane algorithms are not practical for deterministic MIPs, but cutting planes are crucial for the solution of difficult MIPs in a branch-and-cut algorithm (see the article by J. Mitchell in the encyclopedia for an introduction to branch-and-cut algorithms). However, pure cutting-plane algorithms have important applications in the solution of two-stage stochastic MIPs. We refer the reader to the articles by Sen and Hingle [35], for a decomposition algorithm based on lift-and-project cuts for two-stage stochastic mixed-binary programs, Gade *et al.* [36], for decomposition algorithms using Gomory cuts for two-stage stochastic pure integer programs, and Ntaimo [37], for a decomposition algorithm for two-stage stochastic mixed-binary programs based on the so-called Fenchel cuts. (A pure cutting-plane algorithm based on Fenchel cuts [38] is shown to be finitely convergent for deterministic MIPs in [39]. The separation of Fenchel cuts involves the solution of MIP.)

An area closely related to the convergence of pure cutting-plane algorithms is the study of the convergence of *closures* of valid inequalities in MIPs. Given a polyhedron and a family of valid inequalities, the closure of the family of valid inequalities with respect to the polyhedron is obtained by adding all valid inequalities in the family to the polyhedron. Note that the number of inequalities in a given family can be infinite. For example, the family of Chvátal inequalities (which are equivalent to Gomory fractional cuts, not

necessarily constructed from a basis of the LP relaxation) are of the type $\lceil u^\top A \rceil \geq \lceil u^\top b \rceil$ for $u \in \mathbb{R}_+^m$ and the vector ceiling is performed component-wise. Chvátal [40] shows that for pure integer programs, the Chvátal closure is a polyhedron, that is, only finitely many Chvátal inequalities are needed to describe the closure. Moreover, starting with the linear relaxation of a pure integer program, taking Chvátal closures recursively yields the convex hull in finitely many steps. For MIPs, Cook *et al.* [21] show that the split closure is a polyhedron. However, using an example similar to the one given in this article in the section titled “Algorithms using Lexicography and Rounding”, they show that taking the split closure recursively does not yield the convex hull in finitely many steps. Nemhauser and Wolsey [41] show the equivalence between GMI cuts, mixed integer rounding cuts, and split cuts; and as a result, a cutting-plane algorithm based on any of these classes is not finitely convergent for general MIPs. Recently, Del Pia and Weismantel [42] show that for MIPs, the split closure converges to the convex hull in the limit. They also show that the closure of a certain family of cuts called *lattice-free cuts* is a polyhedron and that taking this closure recursively yields the convex hull in finitely many steps for general MIPs. Connections between lattice-free cuts and general multiterm disjunctive cuts are studied in [43], who also give a procedure to construct the closure of the convex hull in finitely many steps. The relationships among the closures of various families of valid inequalities are studied in [44].

ACKNOWLEDGMENTS

The authors thank Suvrajeet Sen for many discussions on convergence of cutting planes and their applications in decomposition algorithms for stochastic integer programs. This work was supported, in part, by NSF-CMMI Grant 1100383.

PUSH AND PULL PRODUCTION SYSTEMS

W.C. BENTON, JR
Department of Management
Sciences, Fisher College of
Business, The Ohio State
University, Columbus, Ohio

INTRODUCTION

The terms Push and Pull are used to describe alternative systems for executing the production process in manufacturing organizations. A Push system is based on forecasted demand that is completed and sent to the next work station or in the case of the final work station, is pushed to finished goods inventory. Specifically, in a push system, work output moves to the next station when it is completed without knowing whether the next station is ready to receive the additional work output. If the succeeding workstation is not ready to receive the new work, excess inventories sometimes result in cost and quality problems. On the other hand, in a pull system, the movement of work is based on the requirements of the following work station. Each succeeding workstation pulls (demands) output from the previous workstation as needed. The next work station determines when and how much output is requested. The output from the final workstation is pulled by customer demand or the master production schedule. In a pull system, work moves to the next station only in response to demand from the next station.

A Hybrid production system combines both Push and Pull production systems. Careful analysis and planning is required prior to implementing this.

In a push production system, the emphasis is on material planning and procurement. In a pull production system, the emphasis is on shop floor scheduling. The hybrid production system thus makes best use of both material planning and shop floor scheduling efficiencies.

There is a common agreement among operations management researchers that JIT functions as a pull system and MRP as a push system. See *Just-in-Time/Lean Production Systems* and *Materials Requirements Planning*. Developed along with JIT, a Kanban system is a production control approach that uses containers, cards, or visual cues to control the production movement of goods through a manufacturing system. Yet, this proposition does not always hold true. For example, Rice and Yoshikawa [1] suggest that there are many practical similarities between the Kanban system and MRP and both are “pull-through” approaches. Also, Karmarker [2] suggests that JIT can be either a pull system or a push system because it is an integral philosophy rather than timing-based manufacturing technique. Summarizing the existing viewpoints on push/pull principles, Pyke and Cohen [3] conclude that an entire manufacturing system cannot be labeled as a push or pull system. They also suggest that the push/pull principles are an attribute of all underlying manufacturing and distribution control systems.

There are *three* ways to define or distinguish the nature of push and pull systems in general. The most common way is to characterize the differences in terms of the order release [2,4,5]. According to this viewpoint, in a pull system, removing an end item (or a fixed lot of end items) triggers the order release, by which the flow of materials or components is initiated. In contrast, push systems allow for the production or material flow in anticipation of future demand.

The second way is to examine the structure of the information flow [6–8]. In a pull system, the physical flow of materials is triggered by the local demand from the next server (individual station). The local demand in this system is signified by the local information (i.e., empty kanbans). In this context, the pure pull system is a decentralized control strategy in which the ultimate goal of meeting demand (orders) is disregarded in the local servers (individual

stations). However, a push system uses global and centralized information. Global information of customer orders and demand forecasts is released and processed to control all the levels of production in the push system.

On the basis of this notion, manufacturing planning and control (MPC) systems may consist of both push/pull elements simultaneously. According to Pyke and Cohen [3], centralized planning systems always have push elements. Therefore, even in the pull-manufacturing environment, outcomes of the central planning decisions may limit certain operating variables of the production control systems. For example, the JIT production system has a push element in setting capacity limit of a batch, the container (bin) sizes.

Finally, the third way to interpret push/pull systems is a practical approach associated with work-in-process (WIP) level on the shop floor. The WIP are orders or materials that have been started in the production process, but are not yet complete. WIP includes orders or materials waiting to be started, orders being setup, orders being worked on, and orders or materials are waiting to be moved to the next work station. A variant of a pull system is the *CONstant Work in Process (CONWIP)* system [9] which is known for its ease of implementation. Stockpiling WIP is a major drawback of MRP systems. In a simulation study comparing push, pull, and CONWIP systems, Spearman and Zazanis [10] found that the merits of the pull system are generated by the bounded WIP, not by the characteristics of pull logic. They show that a hybrid approach, CONWIP, functions in a very similar manner to the pull approach due to its bounded WIP level. Simply, a push system is considered to have infinite production capacity, and a pull system is considered to have finite production capacity. Therefore, the MRP controlled shop floor system without a WIP blocking mechanism would create more WIP inventory than a pull system, unless the production strictly follows the original planned schedule. One of the critical implications of this result is that comparison based on WIP level between an MRP and Kanban system at the shop floor

level may not be fair since WIP level of the Kanban system is inhibited by the size and number of containers.

Based on the three viewpoints suggested above, it can be concluded that if materials flow is initiated by the central planning system without controlling WIP level, the resulting system is close to the pure push system. In a pure push system, the parts or component will precede based on the predetermined schedule regardless of whether the next server is busy or idle. In a pure pull system, the subsequent process will withdraw (i.e., pull) the parts from the preceding process using local information and controlling WIP inventory level.

At the shop floor level, a Kanban system functions as a pull system, and MRP works as a push system. At other levels, the assumption that MRP means push and JIT means pull are not always true. In practice, for example, JIT production systems also use global information for the long-term production planning. The push/pull and MRP/JIT studies are related in a way of deliberating issues associated with material flow. But, MRP or JIT production system plays a role as a structure of a MPC system, whereas push or pull logic is a principle only for material flow in the MPC system. Thus, it is possible for a MPC system to operate under both the push and pull principles simultaneously depending on the stage of production. Notice that the combination of push/pull principles has been adopted and tested in the push/pull integration literature (see Table 1) and Benton and Shin [11]. In this push/pull hybrid-manufacturing environment, the distinction between push and pull is more ambiguous.

KANBAN PRODUCTION CONTROL SYSTEM

The Kanban production system was developed by Toyota. In the most basic Kanban production system, a card is attached to each container of items that have been produced. The container is filled with a percentage of the daily requirements for an item. When the items in the container are used, the card is removed from the container. The

card is the indicator or signal that another container of items is needed. The empty containers are then moved to the storage area. When the container is refilled, the card is attached to the container. The container is then returned to the storage area. The cycle is repeated when the user obtains the refilled container.

In a pull system, work output is based on the demand of the next workstation. A kanban card is used to communicate (signal) the needed demand at the next workstation. Kanban is the Japanese word for card. The kanban card contains a part number, the part description, type of container, and various work station information. A Kanban production control system uses simple, visual signals to control the movement of materials between work centers as well as the production of new materials to replenish those

sent downstream to the next work center. The kanban card is attached to a storage and transport container. The kanban card is used to provide an easily understood, visual signal that a specific activity is required. Kanbans are similar to fixed order inventory systems where an order for Q is placed when the inventory level falls below the reorder point. The reorder point is determined based on the demand during the lead time. The only inventory required is the inventory required during the replenishment lead time.

In a dual-card Kanban system, there are two main types of kanban.

1. *Production Kanban* signals the need to produce more parts. Each kanban is physically attached to a container.
2. *Withdrawal Kanban* signals the need to withdraw parts from one work

center and deliver them to the next work center.

A Kanban controlled manufacturing system functions as a pull system. As discussed earlier, in a pull system, removing an end item (or a fixed lot of end items) triggers the order release, by which the flow of materials or components is initiated. In contrast, push systems allow for the production or material flow in anticipation of future demand.

In some pull systems, other signaling approaches are used in place of kanban cards. For example, an empty container alone (with appropriate identification on the container) could serve as a signal for replenishment. Similarly, a labeled, pallet-sized square painted on the shop floor, if uncovered and visible, could indicate the need to go get another pallet of materials from its point of production and move it on top of the empty square at its point of use.

A Kanban system is referred to as a pull system, because the kanban is used to pull parts to the next production stage only when they are needed. In contrast, an MRP system (or any schedule-based system) is a push system, in which a detailed production schedule for each part is used to push parts to the next production stage when scheduled. Thus, in a pull system, material movement occurs only when the work station needing more material asks for it to be sent, while in a push system the station producing the material initiates its movement to the receiving station, assuming that it is needed because it was scheduled for production. The weakness of a push system (MRP) is that customer demand must be forecast and production lead times must be estimated. Bad guesses (forecasts or estimates) result in excess inventory and the longer the lead time, and more room for error. The weakness of a pull system (i.e. Kanban) is that following the JIT production philosophy is essential, especially concerning the elements of short setup times and small lot sizes, because each station in the process must be able to respond quickly to requests for more materials. The dual-card kanban rules follow:

1. No parts are made unless there is a production kanban to authorize production. If no production kanban are in the “inbox” at a work center, the process remains idle, and workers perform other assigned activities. This rule enforces the “pull” nature of the process control.
2. There is exactly one kanban per container.
3. Containers for each specific part are standardized, and they are always filled with the same (ideally, small) quantity. (Think of an egg carton, always filled with exactly one dozen eggs.)

Decisions regarding the number of kanban (and containers) at each stage of the process are carefully considered, because this number sets an upper bound on the WIP inventory at that stage. For example, if 10 containers holding 12 units each are used to move materials between two work centers, the maximum inventory possible is 120 units, occurring only when all 10 containers are full. At this point, all kanban will be attached to full containers, so no additional units will be produced (because there are no unattached production kanban to authorize production). This feature of a dual-card Kanban system enables systematic productivity improvement to take place. By deliberately removing one or more kanban (and containers) from the system, a manager will also reduce the maximum level of WIP (buffer) inventory. This reduction can be done until a shortage of materials occurs. This shortage is an indication of problems (accidents, machine breakdowns, production delays, and defective products) that were previously hidden by excessive inventory. Once the problem is observed and a solution is identified, corrective action is taken so that the system can function at the lower level of buffer inventory. This simple, systematic method of inventory reduction is a key benefit of a dual-card kanban system. See the kanban determination example given in the next section.

Determining the Number of Kanbans (Containers)

The formula for determining the number of kanbans needed to control the production of a particular product/component part is shown below:

$$\text{Number of kanbans} = \frac{\text{average demand during lead time} + \text{safety stock}}{\text{container size}}$$

$$N = \frac{dL + S}{C}$$

where

N = number of kanbans or containers

d = average demand during lead time

L = lead time; the time it takes to replenish an order

S = safety stock: usually given as a percentage of demand during lead time or the level of expected variance

C = container size

To promote continuous improvement, the container size is usually set at a smaller level than the demand during lead time, say, and 10% of daily demand. This approach will result in reducing the number of kanbans. The reduced number of kanbans causes work methods and process problems to become visible.

Example. Marcus works as an operator at Health First, a supplement manufacturer. He is asked to process an average of 90 bottles an hour through his work station. If one kanban is attached to each container, a container holds 6 bottles, and it takes 20 min to receive new bottles from the upstream work station. The safety stock level is set at 10%. How many kanbans are required for the bottling process?

Solution.

$$N = \frac{(90 \times 0.33) + (90 \times 0.33 \times 0.10)}{6} = \frac{29.7 + 2.97}{6} = 5.44$$

Note: We can either round up or down. If we round down we would be promoting continuous improvement. If we round up we will be allowing more inventory into the process.

Comparison of a Push and Pull Production System

An illustration of the push and pull manufacturing concepts is given in the example above. Traditional MRP manufacturing systems use “push” systems, where the goal is to ensure all workstations and equipments are fully utilized. A result of this is that serial operations (i.e., fabrication, assembly, and finished goods) are independently optimized. Thus, if earlier operations are faster than a later operation, increasing levels of inventory will build at the succeeding work as in Fig. 1a.

As shown in Fig. 1a, overproduction is an element of waste. There are significant

levels of excess raw materials, WIP, and finished goods inventories compared to the pull system shown in Fig. 1b. The resulting excess inventory uses up working capital and is liable to damage and devaluation. The ultimate inventory pile is at the end of the assembly process, where finished goods are stacked up in warehouses, waiting for customers to buy them.

The principle of “pull” is that control is transferred from the beginning of the line to the end. Thus, in the earlier example, Operation B needs to control what is transferred to assembly (Operation B). The secret of this is the “Kanban card.” A kanban card is a control device which effectively says to the recipient

(a)

(b)

Figure 1. (a) Traditional production planning system (push system). (b) JIT kanban production phasing system (pull system).

“Give me N items and N items only. When you have done that, stop! Wait until you get the next kanban card.” The diagram below now shows the changed conversation between the suppliers, Operation A and Operation B. See Fig. 1b.

Operation A now may stand idle for a while, which may seem like a cost, but it is not as great as the cost of idle inventory.

The objective of the pull systems is to see how small number of items you can pull using a kanban. A certain number is needed

to manage natural variation in the process, but no more than minimum needed for the natural variation. Reducing the number of items pulled, even by one, is an effective way of highlighting problems and bottlenecks in the system. For example, reducing the kanban number in the example to five may lead to Operation B being idle sometimes, but if some process improvement is done on it, it may even be able to handle as low as four kanban items. See the kanban determination example on pages.

CONCLUSION

Production control systems are classified as pull and push systems. In a push system, the production order is scheduled and the material is pushed into the production line. In a pull system, the start of each product assembly process is triggered by the completion of another at the end of production line.

There is a common agreement among operations management researchers that the Kanban controlled manufacturing system functions as a pull system and MRP as a push system. In this article, push and pull production systems are discussed.

MRP or JIT production system play a role as a structure of a MPC system, whereas push or pull logic is a principle only for material flow in the MPC system. Thus, it is possible for an MPC system to operate under both the push and pull principles simultaneously, depending on the stage of production. The entry ends with a push and pull MPC illustrations comparison.

QUALITY AND PRICING DECISIONS

CHESTER CHAMBERS
Carey Business School,
Johns Hopkins
University, Baltimore,
Maryland

When firms decide to offer a product or service, they must make integrated decisions regarding the characteristics of the product to be offered and the price that will be charged. This is particularly significant when the characteristics chosen for a product alter or determine a consumer's utility associated with its purchase. An additional layer of complexity exists when quality choices determine the product's production or delivery cost. A major area of scholarly research deals with the simultaneous selection of product quality and price. This research spans the economics, industrial organization, and operations management literatures. Intuitively, it is useful to think of quality in this context as the level of some attribute or some scalar metric representing a vector of attributes (e.g., variety, functionality, and reliability) such that all potential buyers agree that more is preferable to less. With this understanding in mind, it follows that multiple products can be presented to a potential buyer and if these products have different quality levels, it is natural to say that each offering is differentiated from the others. This notion of quality-based or "vertical" differentiation is related to, but distinct from, settings with "horizontal" differentiation. This concept relates to settings in which each buyer type can identify a product that is ideal for him but its purchase by any other type of buyer would provide less utility to that buyer than he could get from buying his ideal product. The relationship between these two notions is discussed in Refs 1 and 2.

In many instances, it is easy to see why a higher quality product would involve greater production or delivery cost. Assuming that the firm is not interested in producing a

product at a loss, it immediately follows that quality choices directly impact pricing decisions. This pair of decisions is made more complex when competing firms offer substitutable products to the same customer pool. In such cases, firms compete in how they "position" their product, where the term position refers to the product's price–quality pair. As an introduction to this topic we will discuss a collection of scenarios in some detail. First, we will deal with a monopolist choosing the profit maximizing quality level and price for a single offering. We initially consider the setting in which quality is free—meaning that production and/or delivery costs are independent of the quality of the offering. We then turn to the setting in which the cost of production is an increasing convex function of product quality. In some cases a monopolist considers multiple product offerings, either to increase profits or to make market entry by a potential competitor less attractive. We offer a few comments on this topic next. Following that we turn to the case of duopolists sharing a single market in which each firm offers a single product to the potential buyers. We then turn to more recent developments in this stream of research and end by highlighting several open questions in the field.

PRELIMINARIES

Several earlier sections of the Wiley Encyclopedia of Operations Research and Management Science provide excellent primers and background material that supplement the discussion presented here. Also, to make the nature of the pricing and quality decisions discussed here precise, we establish the defining assumptions that underlay this discussion below.

Other EORMS Articles of Interest

Speaking most generally, we can say that the quality and pricing decisions under consideration here can be viewed as economic games

involving one or more players. The concept of an economic game is introduced in the section titled “Foundations and Principles of Game Theory.” The objective of the producer of a good in such games is typically quite straight forward, and involves maximizing expected contribution or profit. The objective of the consumer of the good can be much more complex. The section titled “Modeling a Decision Maker’s Preference for Outcomes” discusses how modeling a decision maker’s preference for outcomes has been handled in prior works. Typically, the consumer is not trying to maximize cash flow or the NPV of the outcome of his actions, but some notion of utility that can be derived from the purchase or use of a product being considered. Article on deals with this topic as part of a discussion of SAUT, and, a parallel discussion of multiattribute utility theory is also discussed. An appreciation of these concepts of utility theory is needed to think through the games involved here. To understand how the games will be played out or be resolved, the reader needs an appreciation of the concept of nash equilibria and background on computing nash equilibria (see *Software for Solving Noncooperative Strategic Form Games*). Several additional subtleties of game theory, which are particularly relevant.

Mathematical Background

The marketing and industrial organization literatures often discuss the forces driving product positioning for quality differentiated products via games of vertical differentiation. The economic definition of quality for these settings is an attribute or a scalar, which represents a collection of attributes such that all buyers agree that more is preferable to less. (See, Ref. 1 for a review, and Ref. 3 for a collection of the most frequently cited research.) The notion that quality can be expressed as a scalar value is not as restrictive as it may appear. It can be argued that products are differentiated by a collection of attribute levels, which can be represented by a vector $\mathbf{w}$. Let us assume that this is true. Let us also restrict the discussion to cases in which all feasible products lie in some compact, convex set. Let us define a “generic” good with a quality level of 1. We label this good

y . If we assume that customer preferences are separable between this generic good and characteristics of the product that make it a “nongeneric” good, we can write any individual’s utility function as $u(y, \mathbf{w}) = v(y, z(\mathbf{w}))$. If we are also willing to assume that these $z(\bullet)$ functions are identical across individuals, then we can talk about quality as if it were a scalar. This approach assumes identity at the subutility level but allows individuals to differ in their marginal rates of substitution between the “generic” good and the higher quality good. While this argument is not entirely compelling, it does suggest that treating quality as a scalar value is reasonable even when goods differ regarding multiple attributes. This approach is developed in Ref. 4 and elsewhere. This highlights the fact that quality need not be a physical characteristic at all, but is a concept that relates to the utility that a potential buyer gets from use of the item in question. Consequently, vertical differentiation models have been used to explore a wide variety of differences that increase the demand for a good such as advertising, reputation, or reliability.

To make our discussion easier to follow, we will focus on a set of assumptions that dominate the literature. More specifically, we generally restrict the discussion to settings in which the following conditions hold:

1. We let q refer to the underlying hedonic attributes that characterize a particular product. Thus q is referred to as product quality. As discussed above, q is restricted to one dimension and higher values refer to products of higher quality. When participating firms consider only a single offering at a time, there is a one to one correspondence between product offerings and players in the game. In such settings, no confusion is introduced by referring to “product q ” or even “firm q ” where q refers to either the product or firm offering it.
2. Each customer buys at most one unit of the good or service under study, and has only one reservation price for any particular level of quality. Several researchers [5] have shown that this

assumption is restrictive when considering settings with multiple players or multiple product offerings if the firm's quantity decisions are also included in the analysis.

3. If costs are ignored, there are a fixed number of sellers (typically one or two). Without this assumption, entry could take place repeatedly resulting in a unique product at every quality level with each seller offering a product at marginal cost.
4. Given any finite set of products, all customers possess the same preference ranking for products within that set if they are identically priced. In some settings this is quite natural. If all other things are equal, the automobile offering higher gas mileage is simply better, one razor blade may provide more close shaves than another, one digital camera may record more pixels than another, and so on.
5. Each customer's willingness to pay for quality (θ) or their "taste" for quality is uniformly distributed between some known lower and upper bounds. We label these bounds as $\underline{\theta}$ and $\bar{\theta}$. On some level this is a rather odd assumption. Empirical investigations include Ref. 6, which uses surveys in supermarkets to measure customers' willingness to pay for more tender rib eye steaks. Virtually all customers agree that the more tender steak is of higher quality, but the willingness to pay extra for this difference is clearly not uniformly distributed. Other works [7] argue that the taste for quality is driven by income distributions, and this distribution is also far from uniformity. However, this assumption dominates the literature and offers great advantages at an expositional level. We also note that when considering any single customer, there is a one to one correspondence between his θ value and his utility specification. Therefore, no confusion should ensue when we refer to a customer or its type simply as θ .
6. For each quality level offered, the producer chooses exactly one price. Note

that when comparing two potential customers, say customers A and B , if $\theta_B > \theta_A$ then customer B would be willing to pay more than customer A for the same item. We assume throughout that this type of price discrimination is infeasible for whatever reason. For example, in retail settings, it is simply impractical to attempt to elicit the maximum amount that each customer is willing to pay for each item. Thus, the retailer sets a price for each item and customers either "take it or leave it" based on their internal valuation and the price offered.

7. If costs are invariant in product quality, a maximum achievable quality level $q_{\max}$ exists and is known to all parties in the game. We also make use of the assumption that a minimum allowable quality level $q_{\min} > 0$ exists and is known by all parties. These assumptions guarantee that an equilibrium can exist in such settings. The rationale for the existence of a value of $q_{\max}$ may stem simply from the "state of the art" in the production of the item under consideration. The rationale for the existence of a strictly positive value of $q_{\min}$ may stem from regulatory factors or liability concerns.
8. Market size is assumed to be fixed over time and is normalized to 1. This makes it natural to focus on a representative shopper seeking a single unit of a single good. It also allows us to discuss market shares or demand levels quite easily as functions of q , p , and θ .

Assumptions 5 and 6 imply that the buyer's surplus utility resulting from the purchase of a unit with quality q at price p can be written as $U = \theta q - p$. This utility function has dominated the literature in this field for several decades. However, we discuss an alternate formulation of the problem when considering emerging works.

THE QUALITY AND PRICE SETTING MONOPOLIST

We first consider the setting in which quality is free—meaning that production and/or delivery costs are independent of the quality of the offering. We then turn to the setting in which the cost of production is an increasing, convex function of product quality. In both instances we focus on the profit maximizing selections of price–quality pairs by a monopolist.

Optimal Behavior when Quality Is Free

It is useful here to follow the example developed in Gabszewicz and Wauthy [5]. Consider a monopolist who will choose a price and quality pair for a single offering when production cost is independent of product quality. This assumption is difficult to accept in many manufacturing settings, but does appear to be reasonable in some settings including that for information goods as described in Bhargava and Choudhary [8]. We note that the assumption that production costs are literally 0 need not hold for the following analysis to be relevant; only that the differences in production costs between goods of differing quality levels are negligible. Since any potential buyer's utility level is strictly increasing in product quality, if quality is not costly, the monopolist will offer a product with the best possible quality ($q_{\max}$). It is important to note that when the monopolist offers this quality level, he/she is also choosing the quality level that maximizes social welfare. Thus the only loss in efficiency that arises in this setting is from price selection. Also, consistent with Bhargava and Choudhary [8], we assume that consumers' tastes for quality are uniformly distributed over the interval $[0, 1]$. Now, if a consumer of type θ buys a good with quality $q_{\max}$ and price p , his utility is given by $U = \theta q_{\max} - p$. On the other hand, if he abstains from buying, his utility is simply 0. Therefore, market demand is derived by identifying the consumer θ_1 who is indifferent between the alternatives of buying one unit at price p or not buying at all. Solving $U = \theta_1 q_{\max} - p = 0$, we get $\theta_1 = p/q_{\max}$. Consequently, market demand is simply $D(p, q_{\max}) = 1 - p/q_{\max}$. Since the

monopolist sells his/her output at a per unit price p , we can write his/her profit level as $\Pi = (1 - p/q_{\max})p$. This value is maximized when $p^* = q_{\max}/2$ and the corresponding profit level is $\Pi^* = q_{\max}/4$. Salant [9] and Acharyya [10] have shown that it is sub-optimal for the monopolist to offer multiple products in this setting unless he/she anticipates possible entry by another player. Thus, the highest achievable quality level and a corresponding price level of $q_{\max}/4$ completely describes the outcome in this scenario.

Optimal Behavior when Quality Is Costly

In this section, we build on the approach developed in the seminal work by Mussa and Rosen [11]. One key problem for the monopolist in this setting arises from assumption 5. Given two customer types, say A and B with $\theta_B > \theta_A$, the monopolist knows that type B would be willing to pay more for any product offering than type A . Thus, ideally (from the monopolist's perspective), he/she would charge different prices to the two customer types. However, if this is not practical, then the problem of selecting which products to offer and at what prices becomes more involved. The unit production or delivery cost of any particular quality, $C(q)$, is assumed to be constant for any level of q . In other words, we ignore economies of scale in this development. The unit production or delivery cost is assumed to be an increasing and convex function of product quality. In other words, $C'(q) > 0$ and $C''(q) > 0$. Each customer's surplus utility derived from the purchase of a product is written as $U = \theta q - p$ as explained earlier. Note that if no barriers to entry are present (such as a fixed cost of entry), competition would result in an equilibrium outcome with a product offered at every possible quality level, and this product would be priced at marginal cost. Hence, we would have $P(q) = C(q)$, or market price would equal the production cost for any and all quality levels. Given such a price schedule, each customer type would choose the quality level that maximized his utility. This results in a first-order condition for each buyer of $P'(q) = U'(q) = \theta$. In other words, each buyer purchases a unit such that the marginal cost of increasing the

quality of that unit has the same value as the customer type. Furthermore, each customer type obtains the highest quality good that he/she is willing to buy at his/her marginal cost. The efficiency of such an outcome is quite appealing, but the monopolist finds such an outcome wholly unsatisfactory in that he/she earns no profit. Consequently, it is entirely clear that the monopolist will not work to bring about such an outcome.

To understand how the monopolist will behave, we follow a simple example. Given any continuous, differentiable cost function, it is natural to discuss a curve $C(q)$ that relates cost to quality. For this discussion we let q range from 0 to 1 and assume that $C(q) = q^2$. Now, assume that the market consists of only 2 types of customers, A and B . Let type A have $\theta_A = 0.2$ and let $\theta_B = 1$. The efficient solution includes a product targeting type A with $P(q_A) = C(q_A)$ and $P'(q_A) = \theta_A = C'(q_A) = 2q_A$. Consequently, we end up with $q_A = \theta_A/2 = 0.1$ and $P_A = \theta_A^2/4 = 0.01$. A parallel analysis shows that the efficient solution includes $q_B = 0.5$ and $P_B = 0.25$. Note that type A is left with a surplus of $U = \theta_A(q_A) - p_A = \theta_A(\theta_A/2) - \theta_A^2/4 = \theta_A^2/4$. Similarly type B ends up with a surplus of $U = \theta_B^2/4$.

One approach to understand how the monopolist will behave is to ask how he/she would alter this menu of offerings to extract this surplus from the two buyer types. This directly increases the producer's profits. It is clear that if the monopolist had the power to offer different prices to the different customer types and could restrict each customer type to have access to only one product, he/she would offer quality levels $q_A = \theta_A/2 = 0.1$ and $q_B = \theta_B/2 = 0.5$ and charge respective prices to types A and B of $\theta_A^2/4$ and $\theta_B^2/4$. In this case, the producer maximizes profits and no buyer gets a positive surplus from the purchase of either item. However, this outcome is not feasible if both products are simultaneously offered at these prices and customers are free to choose which product they buy. To understand why, consider the consumer's surplus if type A buys the product which targets type B and vice versa. Type A gets a surplus of $U_A = \theta_A(\theta_B/2) - \theta_A^2/2$. Since $\theta_A < \theta_B$ this value is strictly negative. On the

other hand, $U_B = \theta_B(\theta_A/2) - \theta_A^2/2$ and this value is strictly positive. Thus, if two buyer types exist and the monopolist offers the "efficient" quality levels to the two types and prices them in a way intended to extract all surplus, the high type buyer would prefer the lower quality product. The low type buyer receives no surplus, but the high type buyer receives a positive surplus and reduces the monopolist's profits. Consequently, offering these two product positions is not optimal to the monopolist.

Note that if these two product positions are considered, the monopolist can increase his/her profits by reducing the price of product q_B just enough to entice the higher type buyer to acquire it. This can be accomplished by pricing product B at $\theta_A q_A + \theta_B(q_B - q_A)$. At these price points, the monopolist extracts all surplus from type A and some of the surplus from type B . This is better for the monopolist but still not the best that he/she can do in this setting for the following reason. If the quality of the lower quality good is reduced by a small amount, say Δq and its price is reduced by $\theta_A \Delta q$, consumers of type A are content to buy this new lower quality item and the buyer of type B still prefers the higher quality good. However, the high type buyer is much more sensitive to this drop in quality when compared to the lower buyer type. By reducing the quality targeting type A by an amount Δq the monopolist can actually increase the price charged to type B by an amount $(\theta_B - \theta_A)\Delta q$ without inducing buyers to shift which product type they prefer. Therefore, it pays for the monopolist to reduce the quality offered to "low" types to increase the revenue earned from the "high" types.

Though this example is greatly simplified, its logic applies in general and leads to several important results. First, if $\theta \sim \text{Uniform}[\underline{\theta}, \bar{\theta}]$, then the buyer of type $\bar{\theta}$ is offered the same quality product whether the market is perfectly competitive or served by a monopolist. For every other consumer that the monopolist chooses to serve, the monopolist sells a lower quality good than the buyer would obtain under perfect competition. We reiterate the key point; offering products that lower type buyers will buy makes it impossible for the monopolist to extract all surplus

from the higher type buyers. Consequently, it sometimes becomes optimal for the monopolist to not serve lower type buyers at all. The range of buyer types that the monopolist serves is never greater than that served under perfect competition. Also, for the set of consumers that the monopolist chooses to serve, the difference between maximum and minimum quality offerings is always greater than that would be the case under competition. This is true because the upper end of the quality levels offered is unchanged and the lower bound is always driven downward by the effort to discriminate among buyer types. For any quality level sold both by the monopolist and under competition, the monopoly price is higher than the competitive price and the price differential increases in q . The monopolist uses his/her power to extract as much surplus from consumers as possible. The higher type buyers have more surplus to extract, and the higher the type, the more the monopolist is willing to sacrifice when dealing with low types to get it. Consequently, the higher the type, the greater is the gap between prices charged in perfect competition and that charged under monopoly.

COMPETING DUOPOLISTS

The discussion of the monopolist in the section titled “The Quality and Price Setting Monopolist” raises the natural question as to why the market should contain only one entrant. This question is particularly important if production costs are assumed to be 0. To gain some understanding about how competing firms will behave in such a setting, we consider three scenarios that parallel our earlier discussion. We begin with a treatment of cases in which production costs are ignored. We then turn to cases in which a firm’s fixed cost is increasing and convex in quality but variable costs are ignored. This can be contrasted with settings in which fixed costs are ignored, but variable costs are assumed to be convex and increasing in product quality.

Optimal Behavior of Duopolists when Quality Is Free

The analysis of this problem proceeds slightly differently depending on whether the market

is covered or not, where covered means that each potential buyer actually purchases a product. The setting in which we assume that the market is to be covered dates to the seminal works of Gabszewicz and Thisse [12] and Shaked and Sutton [13]. The notation used is most similar to that described by Tirole [1]. We again assume that the customers’ preferences are described by $U = \theta q - p$ and that $\theta \sim \text{Uniform}[\underline{\theta}, \bar{\theta} = \underline{\theta} + 1]$. We now consider two firms (1 and 2), each of which offers a single product of quality q_i with $q_2 > q_1$. Tirole [1] makes two assumptions in addition to those mentioned earlier.

1. $\bar{\theta} \geq 2\underline{\theta}$. This guarantees that the consumer heterogeneity is sufficient for what follows.
2. $c + \frac{\bar{\theta} - 2\underline{\theta}}{3}(q_2 - q_1) \leq \underline{\theta}q_1$. In this equation the variable production cost is fixed at c . Without loss of generality, we normalize this value to $c = 0$ in the discussion that follows. This guarantees that in the price equilibrium the market is covered. This means that each customer buys one of the two brands offered. It has been argued that this assumption is justified when considering goods or services deemed to be essential.

We note that many subsequent works in this literature normalize the problem such that $\theta \sim \text{Uniform}[0, 1]$. This approach satisfies assumption 1, but violates assumption 2, and guarantees that the market will not be covered. This is clear because for a customer with $\theta = 0$ we have $U = -p$, which guarantees that for some segment of the market no product will be purchased at any price. It is sometimes argued that this is reasonable for discretionary goods since it is clear that not all potential buyers will buy at least one of every type of items offered.

It is natural to model the game as playing out over two stages. In the first stage, firms simultaneously select quality levels. In the second stage they simultaneously select prices. This is consistent with the notion that it is far easier to set product prices than to alter product quality levels. Given quality levels $q_2 > q_1$, it is clear that if all customer

types purchase one item we are interested in cases in which high- θ customers buy the high quality good and low- θ customers buy the low quality good. A consumer of type θ is indifferent between the two products if $\theta q_1 - p_1 = \theta q_2 - p_2$. If we normalize the market size to 1 then, given these assumptions, each firm's market share, or each product's demand, can be equivalently written as $D_1(p_1, p_2) = \frac{p_2 - p_1}{q_2 - q_1} - \underline{\theta}$ and $D_2(p_1, p_2) = \bar{\theta} - \frac{p_2 - p_1}{q_2 - q_1}$. In equilibrium, each firm i maximizes $\pi_i = (p_i - c)D_i(p_i, p_j)$ with respect to p_i . The reaction functions are $p_2 = R_2(p_1) = (p_1 + c + \bar{\Delta})/2$ and $p_1 = R_1(p_2) = (p_2 + c - \bar{\Delta})/2$ where $\bar{\Delta} \equiv \bar{\theta}(q_2 - q_1)$ and $\underline{\Delta} \equiv \underline{\theta}(q_2 - q_1)$. We can say that $\underline{\Delta}$ and $\bar{\Delta}$ are the monetary values of the quality difference to the lowest and the highest type consumers. The Nash equilibrium prices are directly stated as $p_1^* = c + \frac{\bar{\theta} - 2\underline{\theta}}{3}(q_2 - q_1)$ and $p_2^* = c + \frac{2\bar{\theta} - \underline{\theta}}{3}(q_2 - q_1)$. We note that it immediately follows that $p_2^* > p_1^*$. The resulting demand levels are $D_1^* = (\bar{\theta} - 2\underline{\theta})/3$ and $D_2^* = (2\bar{\theta} - \underline{\theta})/3$. In addition, we see that equilibrium profit levels are $\Pi_1^*(q_1, q_2) = (\bar{\theta} - 2\underline{\theta})^2(q_2 - q_1)/9$ and $\Pi_2^*(q_1, q_2) = (2\bar{\theta} - \underline{\theta})^2(q_2 - q_1)/9$.

Now consider the two-stage game in which firms choose quality levels first. The decisions in this stage must anticipate the price equilibrium described above. Note that each firm's equilibrium profit level is monotonic in its selection of quality. Firm 2 wishes to make q_2 as large as possible because Π_2^* is strictly increasing in q_2 . This is also most attractive for Firm 1 since Π_1^* is also increasing in q_2 . Simultaneously, we see that Π_1^* is strictly decreasing in q_1 , as is Π_2^* . Thus, both firms seek "maximum differentiation" meaning that they each benefit from having as large a difference in selected quality levels as possible. Thus, we see that quality-based competition differs dramatically from price-based competition in that the equilibrium results in positive profit levels for both players. Each firm acts as a "near-monopolist" in its own segment of the market. The more dissimilar the two offerings, the less the customers in each segment will value the product offered by the firm serving the other segment.

A study of the second condition shown above shows that cases will exist with a positive lower bound on taste but the second assumption does not hold. In such cases, equilibrium behavior would leave the market uncovered. Choi and Shin [14] offer a comment on the work by Tirole [1] that extends the analysis to this setting. The key difference is that in such cases demand for product 1 can be written as $D_1(p_1, p_2) = \frac{p_2 - p_1}{q_2 - q_1} - \frac{p_1}{q_1}$. The main result is that in this setting the equilibrium will include $q_2 = q_{\max}$ and $q_1 = \frac{4q_{\max}}{7}$. The firms choose a high level of differentiation, but not as great as is possible. The key insight added is that cases exist in which some buyers' taste for quality is so low that the monopolist is better off not serving them even when it is costless to produce a product they would be willing to buy. We explore the rationale behind such behavior on the part of the firm below.

Optimal Behavior of Duopolists when the Fixed Cost of Quality is Increasing and Convex

The assumption that producing a unit of higher quality implies no additional costs is problematic for many product categories. However, in some settings the assumption that variable production costs are not sensitive to product quality while fixed costs, such as product design and marketing expenditures, are does seem reasonable. For example, Bhargava and Choudhary [8] argue that these are quite reasonable assumptions for information goods. To develop insights into this class of problems, we present a discussion motivated by Lehmann-Grubbe [15].

This model considers duopolists competing via a two-stage game in which the fixed costs associated with product quality are represented by a continuous, convex function. In the first stage, the firms choose quality levels. With no loss of generality, we can label the players such that $q_1 \leq q_2$. As assumed earlier, each consumer's utility is expressed as $U = \theta q - p$ and $\theta \sim \text{Uniform}[0, 1]$. What differs here is that the fixed cost of production $C(q)$ is increasing and convex with $C(0) = 0$, $C'(0) = 0$, $C'(q > 0) > 0$, $C''(q) > 0$, and $\lim_{q \rightarrow \infty} C'(q) = \infty$. Given this structure, it is

easy to show that the equilibrium revenue levels can ultimately be written as simple functions of the quality levels of the two product offerings.

$$R_1^* = \frac{q_1 q_2 (q_2 - q_1)}{(4q_2 - q_1)^2},$$

$$R_2^* = \frac{4q_2^2 (q_2 - q_1)}{(4q_2 - q_1)^2}.$$

Note that since $q_2 > q_1$, it immediately follows that the firm offering the higher quality product receives greater revenue in equilibrium. However, this does not prove that this firm will have higher profits because costs rise with quality levels as well. Let us assume for the moment that the firms choose quality levels simultaneously in stage 1 of the game and that a Nash equilibrium exists. In order for this to be the case, we must have marginal revenue equal to marginal costs at the selected quality levels. In other words, we will see

$$\frac{\partial R_1^*}{\partial q_1} = C'(q_1^*) = q_2^{*2} \frac{4q_2^* - 7q_1^*}{(4q_2^* - q_1^*)^3}$$

and

$$\frac{\partial R_2^*}{\partial q_2} = C'(q_2^*) = 4q_2^* \frac{4q_2^{*2} - 3q_1^* q_2^* + 2q_1^{*2}}{(4q_2^* - q_1^*)^3}.$$

To show the main result more clearly let us define $0 < a < 1$ and $0 < z$ such that $az \equiv q_1^* < q_2^* \equiv z$. Thus, the conditions defining an equilibrium can be rewritten as

$$\frac{\partial R_1^*}{\partial q_1} - C'(q_1^*) = \frac{4 - 7a}{(4 - 7a)^3} - C'(az) = 0$$

and

$$\frac{\partial R_2^*}{\partial q_2} - C'(q_2^*) = \frac{4(4 - 3a + 2a^2)}{(4 - a)^3} - C'(z) = 0.$$

The essence of the proof of the main result is that the authors are able to show that the convexity of the cost function along with the equations shown above are sufficient to prove the following:

$$4z \frac{1 - a}{(4 - a)^2} - C(z) > az \frac{1 - a}{(4 - a)^2} - F(az).$$

This, in turn, is sufficient to show that

$$R_2^* - C(q_2^*) > R_1^* - C(q_1^*).$$

In other words, the difference between revenue and production cost for the producer of the higher quality product is greater than the net revenue for the producer of the lower quality product.

Shaked and Sutton [13] argue that this type of setting is a “natural oligopoly” if there is any fixed cost associated with market entry. The firms need to have some distance between their offering and alternative offerings to generate profits. If we envision customer types spread uniformly over some line segment from $\underline{\theta}$ to $\bar{\theta}$, the revenue that a firm needs to cover its fixed costs must be proportional to the length of the line segment that the firm serves. Since the range of consumer tastes is finite, the presence of fixed costs means that the market can sustain only a finite number of competitors. If fixed costs are high enough, the market becomes a natural monopoly and this firm behaves as described earlier.

Additional application and consideration of this model includes the work of Donnenfeld and Weber [16], in which the problem of market entry when the market is large enough to support more than one firm is discussed. In this case if one firm is a first mover, it may be motivated to offer more than one product specifically to cover enough of the market to make market entry unprofitable for a second mover. It is important to note that if firms enter a new market sequentially, each player chooses at most one position, and firms focus only on the competitors present when it makes its positioning decision—the second firm that enters typically earns lower profits than the third. This happens because the first two entrants maximize the quality difference between them. Thus, one firm goes to the top of the quality scale ($q_{\max}$) while the other goes to the bottom ($q_{\min}$). If a third entrant arrives, it takes a position between the two and the resulting equilibrium profit levels have the characteristic that profit levels are increasing in quality. By understanding how the profit levels will evolve if additional players enter a market, an early mover is able

to choose positions that deter others from joining the game.

Optimal Behavior of Duopolists when the Variable Cost of Quality Is Increasing and Convex

Many settings exist in which the fixed cost associated with a higher quality product are not appreciably higher than the fixed cost associated with a lower quality product. In other settings, the fixed cost is sunk by the time the firm considers later decisions, but the variable costs of production vary dramatically with product quality. Gabszewicz and Thisse [12] motivate one of the seminal works in this literature using the purchase of a grand piano as a central example. Many observers including Barron [17] have focused on the production process for these items and found that the product designs for these objects do not change very often but that the variable costs of higher quality offerings do differ dramatically from those of lower quality substitutes because of the use of more expensive materials, higher skilled labor, and different production processes. Consequently, a need exists to consider settings in which the fixed costs of production are sunk but variable costs increase in a convex way with product quality.

The bulk of the research in this literature stream uses a formulation initially presented by Moorthy [18]. This work considers competing duopolists in which each firm's marginal cost of supplying a product of quality q is αq^2 with $\alpha > 0$. Again, it is assumed that customer types are uniformly distributed over some interval $[\underline{\theta}, \bar{\theta}]$, $0 < \underline{\theta} < \bar{\theta}$. The key element here is that the marginal cost of increasing quality grows no slower than linearly. Consequently, a quality level exists at which no producer would consider production because the production cost would exceed the amount that the most quality-conscious consumer would be willing to pay.

As before, we consider a two-stage game. In stage 1, the two firms simultaneously choose quality levels, and in stage 2 they choose equilibrium prices. Consider a setting with three products with three quality levels, $0 < q_1 < q_2$. Selecting a product with a quality level of 0 is synonymous with buying

nothing. If we consider these quality levels to be fixed for a moment, we can identify a customer type θ_1 who is indifferent between buying product q_1 and buying nothing. For this customer, the utility of purchasing product 1 is simply $U = \theta_1 q_1 - p_1 = 0$. Thus, we can see that $\theta_1 = \frac{p_1}{q_1}$. Simultaneously, there exists a customer who is indifferent between purchasing products q_1 and q_2 . For this customer, we will have $U = \theta_2 q_1 - p_1 = \theta_2 q_2 - p_2$. We can solve directly to see that $\theta_2 = \frac{p_1 - p_2}{q_1 - q_2}$. Thus, all customer types with $\theta \leq \frac{p_1}{q_1}$ will purchase nothing. Customers with $\frac{p_1}{q_1} < \theta \leq \frac{p_1 - p_2}{q_1 - q_2}$ will purchase product q_1 . Finally, all customers with $\theta > \frac{p_1 - p_2}{q_1 - q_2}$ will purchase the product with quality q_2 . The first-order conditions for a price equilibrium with $\underline{\theta} \leq \theta_1 \leq \theta_2 \leq \bar{\theta}$ are given by

$$\begin{aligned} p_1^* - \alpha q_1^2 &= \left(\frac{p_2 - p_1^*}{q_2 - q_1} - \frac{p_1^*}{q_1} \right) \left(\frac{q_1}{q_2} \right) (q_2 - q_1), \\ p_2^* - \alpha q_2^2 &= \left(\bar{\theta} - \frac{p_2^* - p_1}{q_2 - q_1} \right) (q_2 - q_1). \end{aligned}$$

Note that these two statements are simply the trade-offs between profit margins and market shares that each firm must serve to maximize profits. Rearranging terms shows that each firm's best price is simply the average of its marginal cost and the price that gives all of the market to its opponent, assuming that this price is greater than marginal cost. Consideration of these two functions simultaneously suggests a price equilibrium at which

$$\begin{aligned} p_1^* &= \alpha q_1^2 + \left[\frac{q_1(q_2 - q_1)}{(4q_2 - q_1)} \right] [\bar{\theta} + \alpha(q_2 - q_1)], \\ p_2^* &= \alpha q_2^2 + \left[\frac{2q_2(q_2 - q_1)}{(4q_2 - q_1)} \right] [\bar{\theta} - \alpha(q_2 + q_1/2)]. \end{aligned}$$

Finally, each firm's equilibrium profits are

$$\begin{aligned} \Pi_1^* &= q_1 q_2 (q_2 - q_1) \left[\frac{\bar{\theta} + \alpha(q_2 - q_1)}{4q_2 - q_1} \right]^2, \\ \Pi_2^* &= (q_2 - q_1) \left[\frac{2\bar{\theta} 2q_2 - \alpha q_2^2 - q_2(q_1 + q_2)}{(4q_2 - q_1)} \right]^2. \end{aligned}$$

With these profit functions in place, it immediately follows that firm 1's optimal

product satisfies the following first-order condition:

$$(q_2 - 2q_1)(4q_2 - q_1)(\bar{\theta} + \alpha(q_2 - q_1)) + 2q_1(q_2 - q_1)(\bar{\theta} - 3\alpha q_2) = 0.$$

The optimal product for firm 2 satisfies

$$q_2(4q_2 - q_1)(\bar{\theta} - \alpha(q_2 + q_1/2)) + (q_2 - q_1) \times (\alpha q_1^2 - 2q_1(\bar{\theta} - 2\alpha q_2) - 8\alpha q_2^2) = 0.$$

The simultaneous solution of these two first-order conditions yields the key result. As long as $\bar{\theta} \geq 2.27505\underline{\theta}$, an equilibrium will exist with $q_1^* = 0.2474\bar{\theta}/\alpha$ and $q_2^* = 0.5288\bar{\theta}/\alpha$. The equilibrium prices turn out to be $p_1^* = 0.109\bar{\theta}^2/\alpha$ and $p_2^* = 0.335\bar{\theta}^2/\alpha$. The resulting profit levels are calculated directly as $\Pi_1^* = 0.0173\bar{\theta}^3/\alpha$, and $\Pi_2^* = 0.0109\bar{\theta}^3/\alpha$. One important observation here is that the producer of the lower quality product earns greater profits in equilibrium. This stands in contrast with the results found when the quality related costs are fixed costs. This is understandable that when we note that the market share for firm 2 increases linearly in q_2 , but its cost increase is convex in q_2 . We also note that as $\bar{\theta}$ increases, the quality equilibrium includes an increase in quality for both products, but the gap between them also increases (if $\underline{\theta}$ is held constant). On the other hand, as α increases, both products decrease in quality, the gap between them decreases, as does profit for both players.

Several important extensions of these ideas have been developed more recently. These include work of Noh and Moshini [19], which considers market entry by a second firm when this entry requires the payment of a fixed fee that is independent of product quality, and both firms' variable production costs are quadratic functions of q . Rhee [20] considers settings in which products are differentiated with respect to quality but are also differentiated along another unobservable dimension. The presence of this unobserved attribute may explain why product positions in practice do not seem to differ as much as economic models

would suggest. Schmidt and Porteus [21] consider the interrelated problems of making investments that probabilistically lead to the ability to offer a product of higher quality and facing higher production cost if the higher quality product is introduced. One process describes the outcome of the investments in technology, while the model developed by Moorthy [18] is used to explain the quality–pricing game that follows.

RECENT DEVELOPMENTS

The work of Moorthy [18] was highly influential in this research stream because it was the first to include production costs in a meaningful way. The formulation in that work assumed that $c(q) = \alpha q^2$. This leads to very specific statements about equilibrium prices, profit levels, and market structures. Several subsequent works build on this foundation to look at related problems. For examples, see Rhee [20], Desai and Srinivasan [22], and Villas-Boas [23]. However, it remains an open question exactly how robust the essence of these results are when a problem setting does not perfectly match the assumptions of Moorthy [18].

Recent work that explores how generally these earlier results hold include that of Jing [24]. This work addresses the question of whether it is more profitable to offer the higher quality product depending on the variable cost function in place. Consider a market with K firms and each firm produces a good of quality q_k at a constant unit cost c_k , and there are no fixed costs. The firms are indexed such that $0 < q_1 < q_2 < \dots < q_K$. Thus each firm occupies a point (c_k, q_k) . The author then develops a way to rank the firms' relative cost efficiency. This is done by comparing each firm's cost–quality pair with those of its closest neighbors. One of the main findings is that the equilibrium profit levels of the firms will match the ranking of the relative cost efficiencies. The basic message is that if a firm's cost does not rise “too fast” with an increase in quality, the higher quality product will be more profitable. Of course, the phrase “too fast” must be understood relative to its closest competitors.

Recent work by Chambers *et al.* [25] explores the impact of altering the distribution of consumer taste among the population, to consider $U = \theta q - p$ when $f(\theta) = 1/\theta^2$ and $\theta \in [1, \infty)$. By dividing both sides of the utility function by θ and rescaling the problem, their work approximates the utility function by using $U = q - \theta p$ with $\theta \sim \text{Uniform}[0, 1]$. This simple transformation yields at least three unexpected and interesting results. First, allowing θ to be uniform on $[0, 1]$ accommodates problems with either covered or uncovered markets. Second, on the basis of the assumptions made in Chambers *et al.*'s work, the equilibrium price for the lower quality good equals the production cost of the higher quality good. This is a critical point, because it shows how the management of cost for one player affects the ability of its rival to manage the margin on its product offering. Third, their work finds that the behavior of competing duopolists leads to an equilibrium in which the profit level for the producer of the higher quality good is $\Pi_2 = q_2 - q_1$. This is true because the producer of the high quality good maintains enough price flexibility to drive the equilibrium price for the low quality good to the cost level of the high quality product. This fact allows the higher quality producer to compete "purely" on product quality. Thus, the quality gap defines his/her profit level.

The question of whether the market is covered or not is a bit more complex. It is easy to produce cost functions that produce either outcome. However, the authors are able to prove another useful result. If $c(0) = 0$, $c(q)$ is strictly increasing, twice differentiable, and convex on $[0, q_{\max}]$, and the average variable cost function $c(q)/q$ is convex and log-concave on $[0, q_{\max}]$, then the producer of the lower quality good earns higher profits when $q_L \leq c_H$. In addition, the authors show that it is never optimal for the lower quality producer to offer a product with a quality level above the minimum level that would cover the market for this class of cost functions. This result was developed assuming that both firms have identical cost functions, but does not assume any particular functional form. However, there is really no convincing argument that the cost functions

must always be equivalent. An extension of this work by Chambers and Ramachandran [26] has shown that this result holds even when the firms have different cost functions of the form $\alpha_i q_i^{r_i}$ where α_i , q_i , and r_i are each firm specific.

Underdeveloped Research Areas

Several important topics remain underdeveloped in this research stream. First, it is important to relax the assumption that all players in an industry and those considering market entry have identical cost functions. Many explanations are available which explain why firms have differing cost functions including learning effects, exchange rates, investment levels, and other elements of firm strategy. It is also important to consider both fixed and variable costs simultaneously. Many automated production approaches have higher fixed cost but lower variable cost when compared to older, "craftsman"-based systems they may be replacing. On the other hand, many emerging economies leverage their lower labor cost to use more labor-intensive approaches to compete with incumbent firms. Consequently, price-quality decisions are actually intertwined with technology management and/or outsourcing decisions.

Another important issue is that there is no good reason to believe that the distribution of taste parameters among consumers is stagnant. Consumers' expectations regarding product quality evolve over time and experience may drive the average taste upward for some items and downward for others. This could drive down the appeal of the lower quality good over time unless the quality of that offering keeps pace with changing consumer sentiment. Just as likely, it could force the producer of the higher quality good to lower his price over time if $q_{\max}$ cannot consistently be raised. Another problem is that deteriorating economic conditions may alter income distributions. This may serve to drive consumer tastes downward, increasing the market share of a lower quality offering. This may explain why sales at Wal-Mart and McDonald's rise while sales at Neiman Marcus and many exclusive restaurants decline during recessionary periods.

While this article has focused on the modeling of quality and pricing decisions, we would be remiss if we do not mention the need for empirical validation of the underlying assumptions embedded in these models. Some models do assume a general distribution of taste parameters but some nuances of the problem of product positioning must be sensitive to the functional form of that distribution. On the other hand, it is not at all clear that firm behavior is consistent with the economic conclusions. Stronger connections between economic models and firm practice is always enlightening.

QUALITY DESIGN, CONTROL, AND IMPROVEMENT

AMITAVA MITRA
College of Business,
Auburn University,
Auburn, Alabama

INTRODUCTION

Quality is fundamental to the success of all manufacturing and service processes. Management plays a critical role in ensuring quality in all phases, be it in the design of products/processes, the manufacturing of products or delivery of services, or in the operational phase of the product when used by the consumer.

This article links the concepts of quality design, quality control, and quality improvement (QI) and provides a perspective on the role of each of these functions. These functions are inter-related to each other and knowledge from subsequent phases is used as a feedback to ascertain action plans in the individual phases. Hence, creation of a quality design incorporates information from the processes that will be used to produce the product. Further, if product performance when actually used by the customer is not acceptable, it may influence design quality as well. In the following sections, the article describes the concepts of quality design, control of quality, and QI, respectively. An overview that links these functions is first presented.

QUALITY OF DESIGN, CONTROL, AND IMPROVEMENT FUNCTIONS

It is well understood that quality plays an important role in the production and performance of a product or the delivery of a service that meets the needs of the customer. The functions of designing a quality product or a process, maintaining stability in the process, and creating modifications to the product or

process design to adapt to the dynamic needs of the customer are integrally related to each other. The functions of quality design, quality control, and QI work in unison, each influencing and being influenced by the others.

Figure 1 provides a view of the conceptual linkage between the quality design, control, and improvement functions. As with any product or service, the first and foremost goal is meeting or exceeding the needs of the customer. Three prioritized categories of needs exist. Firstly, basic needs are those that are absolutely expected by the customer. While meeting these needs will not necessarily improve customer satisfaction, not meeting them will create a dissatisfied customer. Secondly, performance needs, on the other hand, typically influence customer satisfaction in a linear manner. Thirdly, excitement needs influence customer satisfaction exponentially. Such needs may not even be known or expected by the customer. Hence, their satisfaction thrills the customer.

All product/process designs are constrained by the availability of a limited budget. Further, it must be feasible to manufacture the product incorporating the developed design. Thus, product and process design go hand-in-hand. Once a feasible product and process design is established, the manufacturing phase must take place. Here also, there are constraints imposed by demand for various products, availability of raw material and parts, lead time for vendors, and availability of resources imposed by schedule constraints. The function of quality control deals with ensuring that the process is in a state of statistical control, that is, only common causes inherent to the system exist. Control chart methodology is used in this context. Even if a process is in a state of statistical control, it is still possible for the product to not meet the specifications as desired by the customer. If this is, in fact, the case, we conclude that the existing process is not capable and seek QI strategies

Figure 1. Linking quality design, control, and improvement functions.

to further improve product and/or process design. The eventual test of quality is based on how well the product functions when used by the customer. Issues such as failure within the warranty period merit consideration. Therefore, a feedback loop also exists for development of QI strategies based on field performance of the product.

QUALITY OF DESIGN

Designed quality in a product may be accomplished in a variety of ways. Resource availability, feasible manufacturing processes, and vendor quality are the factors that influence product quality. We first discuss the process of incorporating customer needs into the design of the product using the technique of quality function deployment (QFD). Thereupon, some concepts are illustrated on improving the system reliability of a product as most products are basically comprised of subsystems/components.

Quality Function Deployment

The central focus is on designing products that meet customer needs, and the product development cycle accomplishes this through a series of steps known as *QFD* [1]. QFD is essentially a planning tool that starts with product design to meet customer needs, continues to analysis of parts and components to create the desired product, progresses to process design, and eventually ends with production requirements. In each of these phases, a procedure utilizing the *house of quality* (HOQ) [2,3] is utilized. We briefly discuss this procedure in the context of product design. A similar approach could be used in the other phases as well.

In product design, a core concept is to prioritize customer requirements, usually through some ratings scale, such as a Likert scale with ordinal ratings of 1–5, with “5” representing “most important.” Thereafter, a relative assessment is performed, with respect to chosen competitors, on customers’ perceptions on each of the selected requirements. Such ratings are also on an ordinal scale, say 1–5. Review of the ratings indicates

the benchmark organization, for each of the customer requirements, and the relative standing of the company with respect to its competitors in satisfying each customer requirement. An outcome of such analyses could be to identify a desirable approach to pursue, to meet each of the requirements.

The next step in the procedure is the identification of technical product descriptors that will address the customer requirements. Attention should be given to satisfy critical customer needs first, as depicted by the priority ratings, and arriving at a small and cost-effective number of product features. It is possible for a given product feature, known as a *technical descriptor*, to satisfy more than one customer need. Following this is the assignment of rating factors of each technical descriptor to each customer need, using an ordinal scale of, say, 1–5, sometimes known as the *relationship matrix*. A zero may be assigned if the technical descriptor has no impact on meeting the particular customer requirement.

Using the relationship matrix, for each technical descriptor, the product of the customer importance rating of the requirement to the assigned rating score for the technical descriptor to meet the requirement, is found, and added up to determine the effectiveness of the particular product feature in meeting all customer requirements. A comparison of the sum of the weighted rating scores for each product technical descriptor provides us with an indication of their relative effectiveness in satisfying customer needs and also with management decisions to select the appropriate product descriptors, if all of them are not cost-feasible.

Additionally, a technical competitive assessment of the product descriptors may also be conducted. In this step, using an ordinal rating scale, say, of 1–5, the relative assessment with respect to the competitors may be performed for each descriptor. Rather than using customer information, this step addresses technical competence and the corresponding benchmark (or leader), for each product descriptor. It demonstrates the relative strengths and weaknesses of the company and areas, in terms of product features, where improvement efforts should

be focused. When technical information on competitors is publicly available, information from this step may be used along with the sum of the weighted rating scores for each technical descriptor, to make decisions regarding choice of product features.

System Reliability

Product designers are obviously interested in creating a design that not only meets but also exceeds customer expectations. With this goal in mind, a couple of constraints limit the designer. Resource availability and the availability of existing manufacturing processes are two major constraints. One basically has to address the question: Can we make what we designed within our allocated budget and available technology? The answer to this question is what creates a feedback loop between product design and process design. If we cannot make what we designed, the design may have to be altered considering the technology that is available, which is precisely the concept of *design for manufacturability* [4].

Most products consist of components or subassemblies that are assembled in a desired configuration for proper functioning of the product. To satisfy the customer, it is the reliability of the end product that is of interest. The reliability of a product or component represents the probability of it functioning effectively for a certain period of time under certain environmental conditions. The complexity of the configuration of components that create the end product will impact the reliability of the end product or the system of components. Let us examine the various factors that affect system reliability.

First, raw material quality, resource availability, and available technology will influence the component reliability. Manufacturing capability, as discussed earlier, will impact component reliability. As variations exist in all manufacturing processes, component reliability for a selected time period is always less than one. Second, component configuration greatly impacts reliability. For example, if components are in series, implying that all components must function for the system to function, the system or end product reliability is the product of the individual

component reliabilities, assuming that the component failures are independent of each other. Hence, if there are 20 components in series, each with a reliability of 0.990, the system reliability is only 0.818.

Several options exist for improving system reliability through design. One is the concept of adding components in parallel, creating redundancy in the system [5]. In this situation, the system or end product functions so long as at least one of the components, which are in parallel, functions. Suppose that there are p components in parallel, including the original component. Denoting the reliability of each component by R_i and assuming that the components operate independently of each other, the system reliability is given by

$$R_s = 1 - \prod_{i=1}^p (1 - R_i). \quad (1)$$

Consider an example where there are five components in parallel, each with a reliability of 0.8. The system reliability is greatly improved to 0.99968. As resource availability and manufacturing capability are usually bound on the reliability of a component, the concept of using a redundant design greatly improves system reliability. Of course, the product unit cost increases because of the added components.

A second concept, similar to the redundant design, is that of incorporating standby components in parallel. In this design, it is assumed that only one component in the parallel configuration is operating at any given time. In a parallel system, all components are assumed to operate simultaneously. Hence, system reliability for standby systems is higher than that of comparable systems with components in parallel. Suppose that the time to failure of components is an exponential distribution with failure rate λ , which amounts to the number of failures in time t following a Poisson distribution with parameter λt . Therefore, the probability of x failures in time t is given by Mitra [5]:

$$P(x) = \frac{e^{-\lambda t} (\lambda t)^x}{x!}. \quad (2)$$

Now, if we have a standby system with the basic component and n standby components, the system reliability is given by

$$R_s = e^{-\lambda t} \left[1 + \lambda t + \frac{(\lambda t)^2}{2!} + \cdots + \frac{(\lambda t)^n}{n!} \right]. \quad (3)$$

QUALITY CONTROL

There are two types of cause systems that influence manufacturing and service systems—*common causes* and *special causes*. Common causes are those that are inherent to the system. While they cannot be completely eliminated, their impact may be reduced through the design of better processes, equipment, procedures, raw material, and components. For example, variation of a certain characteristic, say part length, will always exist. The degree of variation may be reduced through *QI* efforts. *QI* thus deals with making systemic changes to improve products and processes.

Special causes, sometimes called *assignable causes*, are not inherent to the system. They occur due to some changes in the process that, hopefully, can be identified so as to take appropriate remedial action to eliminate them. In the manufacture of the part length, a new operator could be using a feed rate different from the specified norm, which may increase the variability and/or change the average value of the surface finish. The detection of such special causes and subsequently the identification of remedial actions may be facilitated through the process of *quality control*. In particular, *statistical process control* (SPC) deals with the monitoring of processes through statistical methods known as *control charts*. A process is said to be in statistical control when only common causes prevail in the system.

Control charts may be broadly classified into two categories—those for variables and those for attributes. Quality characteristics for variables are those that are measurable on a numerical scale. The length, thickness, surface finish, and tensile strength of a part are examples. For variables, the type of information collected from the process typically

dictates the type of control chart. Further, the formation of rational subgroups to collect data from the process is an important consideration. The idea is to choose subgroups such that the variation within subgroups is minimized, while the variation between subgroups should be used as a guideline to maximize the chance of detection of an out-of-control process.

Control charts typically have three reference lines: a center line that is usually an estimate of the mean of the quality characteristic and two bounds indicated by a lower control limit (LCL) and an upper control limit (UCL). These bounds are selected based on a chosen level of Type I error or false alarm in making decisions from the control chart. For quality characteristics that are variables, if each subgroup contains more than one observation, the guidelines are to construct a control chart for the mean ($\bar{X}$) and range (R), when the subgroup size is small (≤ 10). For large subgroup sizes, control charts for the mean ($\bar{X}$) and standard deviation (s) may be monitored. When each subgroup has only one observation, control charts for individuals (I) and moving range (MR) are used.

The second category of control charts is for attributes. Here, one class of control charts deals with the situation where the product or item is classified as conforming or nonconforming. The proportion nonconforming (p) chart is used when the subgroup size may remain constant or vary from one subgroup to another. The number nonconforming (np) chart is used when the subgroup size remains constant. A second class of control charts deals with the monitoring of nonconformities or defects. In this context, if the subgroup size remains constant, the c -chart for monitoring the number of nonconformities is used. On the other hand, if the subgroup size varies, the appropriate control chart is the u -chart that monitors the number of nonconformities per unit. An important consideration in attribute charts is the choice of an adequate subgroup size. The subgroup size must be large enough for nonconforming items or nonconformities to occur. A rule of thumb is that the expected number of such nonconforming items or nonconformities should be at least five. Details of SPC or statistical

quality control (SQC) are found in Statistical Process Control Section 4.1.5.3 of the encyclopedia.

A major objective of the control charting scheme is to determine the presence of special causes and take remedial action, as soon as possible, to bring the process back to a state of control. A process in control, therefore, is impacted by only common causes. Does this mean that if we have a process in control the customer satisfaction level is high? Not necessarily. There is a conceptual difference between a *process in control* and a *process that is capable*. *Process capability* addresses the degree to which the product, with the corresponding attributes, meets the requirements of the customer. A process can be in control but not be capable. Measures of process capability are found in Statistical Process Control Section 4.1.5.3 of the encyclopedia. Process control could be conducted on-line or off-line. In order to minimize the impact on outgoing product quality, for a process that is out-of-statistical-control, remedial action should be taken as soon as possible. For this reason, SPC through control charts, where feasible, could be implemented on an on-line basis.

QUALITY IMPROVEMENT

While quality control involves the identification of special causes and implementation of remedial actions to bring the process to a state of control, QI addresses the issue of the product or service meeting the needs of the customer. A process could be in statistical control yet the product may not satisfy customer requirements. This occurs when the inherent variation in the process, as defined by its natural tolerance limits, exceeds the variation as allowed by the specification limits. In such cases, the product and/or process may have to go through the design phase again so that the redesigned product manufactured by a redesigned process will meet customer specifications. QI is incorporated through such a feedback loop (as previously demonstrated in Fig. 1). Moreover, actual field results from the performance of the product when used by the customer may

also demonstrate a need for QI. For instance, field results may demonstrate a higher proportion of product/component failures within the warranty period. On identification of the causes of product failure, a product may have to be redesigned to avoid the repetition of early failures.

In the design phase of products and associated processes, one may identify the settings of process parameters that will lead to the accomplishment of desirable levels of the product parameters. Such analyses may be conducted off-line, much before production runs are implemented. It may be conducted through prototype runs of the process where it is feasible to change process parameter settings. Product output results could be obtained for such trials and analyzed to identify process settings that accomplish the product characteristic to be close to the target value and possess variability as small as possible. The topic of *design of experiments* (DOE) using statistical analysis is a viable approach for this off-line approach to QI.

Quality and Competitive Position

In the twenty-first century, importance of continual QI in order to stay competitive is paramount. Here, we discuss some specific ways in which improved quality affects the competitive position of the organization and improves its relative standing. In particular, we consider price/cost ratio, capacity, and market share.

With an improvement in the level of quality, there are fewer rework and scrap items and fewer returns by the customer. The unit cost of producing a conforming product decreases. Even if the unit selling price of the product does not change, the unit margin on the price/cost ratio improves, which leads to increased profitability of the organization.

An improvement in the quality level implicitly creates additional capacity. As there is a reduction in the amount of rework and scrap items, additional capacity (resources) will not be necessary to make up for items lost due to rework and scrap, assuming the demand to remain the same. Hence, the company will be able to produce more products to meet customer demand,

without necessarily going into overtime or subcontracting. In a sense, the company has been able to “increase capacity.” This leads to a more efficient utilization of the available resources.

A direct effect of the impact of an improvement in quality is increased customer satisfaction. As always, increased customer satisfaction may improve the firm’s ability to not only retain existing customers but also to draw customers from competitors. A positive impact is therefore a growth in market share. Another indirect impact is the ability to manage the unit price/cost ratio. With improved quality, the customer may be willing to pay a higher price. Thus, the profit margin is impacted in three ways. A higher unit price could be charged, a lower unit cost is achieved due to QI, and the market share is increased due to increased customer satisfaction. The contribution to total profit, in a simplistic sense, may be expressed as:

$$\begin{aligned} \text{Total profit} &= (\text{Unit price} - \text{Unit cost}) \\ &\quad \times \text{Market share,} \end{aligned} \quad (4)$$

where all three components on the right-hand side of the equation may be impacted through QI. Manufacturing a product usually requires many operations in sequence. The proportion nonconforming of the finished product is, thus, a function of the quality level of each operation and the number of operations. Let q_i be the quality level (proportion conforming) in operation i . Then, the proportion nonconforming at the finished product level, when there are n operations, is

$$p = 1 - (q_i)^n. \quad (5)$$

Hence, for a process with 30 operations, even if each operation is 99% conforming, the finished product is about 26% nonconforming, assuming that the operations are independent of each other. Sometimes, this assumption may not hold. In other words, a product that is nonconforming at stage j , may impact the rate of nonconformance in stage $(j + 1)$ adversely. This leads to an important consideration. What should the quality level be at a given operational stage?

Six-Sigma Quality

The notion of six-sigma quality [6] attempts to address this issue. Six-sigma may be viewed as a philosophy, methodology for continuous improvement, or as a metric of performance.

Let us consider its interpretation as a metric. Assuming that the distribution of the product characteristic is normal and that the product specification limits are three standard deviations from the mean, the proportion of nonconforming product is about 0.27% or 2700 (parts per million). As explained previously, the compounding effect of the number of operations comes into play. Thus, for a product with a 1000 parts or one that has 1000 operations, an average of 2.7 defects per product unit is expected. The rolled throughput yield, a measure of proportion conforming, is quite small.

If the specification limits are each six standard deviations away from the mean, the proportion nonconforming is only about 0.001 ppm on each tail, using the normal distribution. This quality level seems quite good compared to the 2700 ppm for a three-sigma capability level. In real-world situations, a process may drift (i.e., a shift in the location to the right or the left). Allowing for a shift in the process mean of 1.5 standard deviations from the center, the nearest specification limit is 4.5 standard deviations from the process mean. Using normal distribution theory, the proportion nonconforming is about 3.4 ppm, accounting for this drift. Hence, when six-sigma is viewed as a metric, with a nonconformance rate of 3.4 ppm, it should be noted that the nearest specification limit, for this situation, is 4.5 standard deviations away from the mean and not six standard deviations.

As a philosophy, six-sigma may be considered as a strategic initiative for organizations. It prescribes a road map to pursue the goal of continuous QI. The pursuit of quality is a never-ending journey. As with other approaches, the customer will be the key factor, with analysis of products and processes to improve customer satisfaction as the goal.

When six-sigma is considered as a methodology, it defines a sequence of logical steps to adopt to accomplish QI. In this context,

the *define, measure, analyze, improve, and control* (DMAIC) approach [7] becomes relevant. In the define phase, customer needs are translated to specific attributes that are critical to quality, cost, or delivery. Prioritization of needs as dictated by the customer will create a relevant focus. The measure phase creates metrics, which are measurable, for tracking process performance. Existing baseline levels may be used to determine if significant improvements occur based on the recommended action items. The analysis phase involves statistical analyses of collected data from the process to gauge the level of improvement. Sometimes, these may be simple graphical tools such as scatterplots, histograms, or multivariable charts. Subsequent analysis could be on hypothesis testing of process parameters, regression analysis of a selected response variable, or analysis of variance to investigate the significance of one or more factors on a chosen response variable. In the improve phase, identification of significant factors and their optimum levels is of interest. Finally, in the control phase, methods are identified to sustain the gains accomplished in the preceding phase. Statistical control charts, as found in Statistical Process Control Section 4.1.5.3, could be used in this context.

Quality Improvement Tools

Some simple graphical tools aid management in the QI process. One is the use of *Pareto diagrams* (based on the principle that 80% of the problems are created by 20% of the causes), which prioritize problems by arranging them in decreasing order of importance. A valuable tool in investigating process efficiency is the *flow chart*, which represents the sequence of events in a process. Analysis of a flow chart may lead to process simplification, identification of bottlenecks, and elimination of nonvalue added activities. A refined version of the flow chart is the *process map*, which may reflect the inputs and outputs for each event, the critical, controllable, and noise parameters for that operation, and the person who has ownership of that process.

An effective tool in QI is the *cause-and-effect* diagram, often known as a *fishbone diagram*. In this diagram, the problem of

interest, or the effect, is brainstormed to identify major causes. Major cause categories, for example, could be material, methods, people, machines, measuring equipment, and environmental factors. For each major cause, depicted graphically such as a fishbone, subcauses are listed. A QI team considers such causes and subcauses to identify ones that should be investigated.

Bivariate data in the form of a *scatterplot* depicts relationships between two variables. These may be used as a follow-up to a cause-and-effect analysis to obtain the impact of a controllable factor on an output characteristic. As realistic products and processes often involve more than two variables of interest, which includes dependent and independent variables, *multivariable* charts could be insightful. A *matrix plot*, for example, could depict how each independent variable impacts a given dependent variable, based on which a decision could be made on the independent variables to control.

Taguchi Loss Function

A traditional definition of quality is conformance to specifications. As long as the quality characteristic is within specifications, no loss is incurred. Therefore, for a characteristic with two-sided specifications, an upper specification limit (USL) and a lower specification limit (LSL), the loss is zero for the region between LSL and USL. For regions outside the specification limits, a constant loss (L_0) is encountered (Fig. 2).

This notion of a step-function loss is difficult to justify because the loss associated with a product whose characteristic is just above the LSL is zero, while for that which is just below the LSL it is L_0 . Moreover, under this definition of loss function, there is no motivation to improve quality as long as the characteristic is between LSL and USL.

The loss function advocated by Taguchi is more realistic [8,10]. A loss is incurred anytime if there is a deviation of the quality characteristic from the target value. This loss function is indicated by L_1 in Fig. 2. Losses may arise owing to customer complaints, warranty costs, lost opportunities, and other tangible and intangible costs. The

Figure 2. Comparison of old and new measures of the loss function. [Source: Reprinted with permission from Ref. 5. Copyright 2008 Wiley & Sons].

equation of such a loss function is given by

$$L_1(y) = k(y - T)^2, \quad (6)$$

where y represents the value of the characteristic, T is the target value, and k is a proportionality constant. Knowing the cost (or loss) to replace a product whose dimension is just below the LSL to be A , we obtain

$$k = A/\Delta^2 \quad (7)$$

where $\Delta = T - \text{LSL} = \text{USL} - T$ (assuming the target is centered within the specifications).

A feature of this loss function is that it promotes the philosophy of continuous improvement to reduce loss as the loss function increases with deviation of the process mean from the target value and with process variability.

Experimental Design

In classical experimental design [9] the primary objective is to create a model of

the response variable, that is, the quality characteristic in which we are interested, as a function of several factors, which are usually process variables. The predictors could be process variables and/or some functions of them as well as possible interactions between them. The objective is to develop a model for the mean response and thereby determine the significant predictors and their levels to accomplish a desired value for the mean response.

On the other hand, the Taguchi method of experimental design has an objective of not only achieving a desired mean response but also reducing the variability in the quality characteristic. Furthermore, this approach incorporates not only the process parameters but also the uncontrollable or noise factors.

As all processes have variation, the focus of the Taguchi concept is on robust designs, which are less sensitive to the uncontrollable or noise factors. While noise factors cannot be completely eliminated, Taguchi's approach to experimental design is to determine the settings of the noise factors and the controllable factors such that variability is minimized and

the quality characteristic is close to the target value. The performance measure used in Taguchi's experimental design is usually in the form of a signal/noise (S/N) ratio, that is maximized, and appropriate factor level settings are determined [10]. Thus, for the squared loss function, the signal is proportional to the squared difference between the process mean and the target (for a two-sided specification), while the noise is proportional to the variability of the characteristic.

Even though noise factors are uncontrollable, for the experimental design that investigates the settings of the controllable and uncontrollable factors and their impact on the response variable, Taguchi advocates selections based on joint considerations of these variables. The matrix settings of the controllable or design parameters are chosen in an inner array. The noise factor settings in the designed matrix are in an outer array, and these serve as replications for each setting of the design factors.

There are four basic phases in designing an experiment. In the planning phase, the factors or variables to be considered in the study along with the response variable, the levels of the factors, and the number of replications deserve consideration. Ideally, the runs should be selected in a randomized order to average out the effect of all other factors not considered in the analysis. Practical limitations on the process, for example, changing the temperature setting in an oven from a low to a high setting (skipping the medium setting) may cause restrictions on randomization. While more replications, for a given factor combination setting, are desirable, cost considerations may influence this choice.

One major advantage of a designed experiment is the ability to estimate *interaction* effects between factors. This represents the joint impact of factors on the response variable. For an experiment with two factors, for example, Factor A and Factor B, each at say two-level (low and high), interaction represents the degree of change in the response variable, as Factor A changes from a low to a high level, for a chosen level of Factor B. If the degree of change is different, for different levels of Factor B, an interaction is said to exist

between Factors A and B. In addition, if the interaction effect is significant, decisions on the optimum factor levels are based on such analyses rather than from the main effects.

The second phase in a designed experiment is that of process characterization or screening. This involves identification of significant factors from a multitude. Here, the choice of factor levels is kept minimal, say two or three, with usually the extreme values of the range of the factor level being selected. Taguchi designs could be used because they utilize a few factor levels and the total number of runs is quite small relative to the total number of factors chosen. For example, a 15-factor experiment with each factor at two levels may require only 16 runs using an orthogonal array. Experimental designs used in the Taguchi approach make use of orthogonal arrays. Such arrays have the property that every factor setting occurs the same number of times for every test setting of all other factors. In the design matrix setting, each row represents the levels or settings of the chosen factors (a run), while each column represents a specific factor. Any two columns of an orthogonal array form a two-factor full factorial design. Use of orthogonal arrays minimizes the number of runs while retaining the pairwise balancing property. An example of an orthogonal array for three factors, each having two levels (1 and 2), is shown in Table 1 with four experimental runs.

The third phase is that of optimization that involves determination of the optimum levels of significant factors to achieve desired characteristics associated with the response variable. As discussed previously, the S/N ratio is a performance measure considered in

Table 1. Orthogonal Array for a Three-Factor Experiment

Experiment	Factor 1	Factor 2	Factor 3
1	1	1	1
2	1	2	2
3	2	1	2
4	2	2	1

the Taguchi approach. Lastly, the verification stage follows where the selected optimal settings of the factor levels are chosen to observe values of the response variable or performance measure to confirm actual process performance under these settings.

QUALITY MANAGEMENT

AMITAVA MITRA
College of Business, Auburn
University, Auburn, AL

INTRODUCTION

What exactly is quality? A traditional definition, given by Crosby [1], relates to conformance to requirements or specifications. Such a definition focuses on some pre-designated standards for the product. Juran [2] proposed a more general definition incorporating fitness for use. Garvin [3], on the other hand, considered the definition of quality in five categories: product-based, user-based, manufacturing-based, value-based, and transcendental. At the core of product/service quality is the satisfaction of the customer. Hence, we advocate a definition of quality that incorporates meeting or exceeding the needs of the customer [4].

Management of the quality function is critical at all levels of the organization. Senior management sets the vision, mission, and associated strategic plans to accomplish the mission. They must also address aggregate costs, market share, and unit profitability so as to provide a reasonable rate of return to investors/shareholders. In this context, the role of quality in reducing unit total costs is discussed. Middle management usually deals with tactical issues. Whether it is determination of unit price, product mix, or product servicing after it is sold to the customer, product quality impacts such decisions. Line management deals with operational issues. Specific processes and their parameters, as well as desirable technical traits of employees involved in making the product, are issues related to quality considered at this operational level. Vendor quality of materials, components, and sub-assemblies also influence product quality.

Responsibility for quality, therefore, lies with everyone involved in the various phases

of product/process design, manufacturing, process control, product servicing on sale of the product, and meeting of customer needs. Identification of the customer is a first step that is assisted by knowledge of the market and competition. It should be noted that as both market and competition are dynamic in nature, customer identification is an iterative process that incorporates the changing nature of these entities. Consider a manufacturer of high end automobiles. It is incumbent on the manufacturer to identify the target customer group for such automobiles and possible factors that describe this group. These could be a base income level, an age classification level, or status of home ownership. Market research plays a key role in the identification of product features and characteristics that the customer prefers. The product design team faces the challenge of creating a feasible product that meets the requirements of the customer. Thereupon, process design ensures the feasibility of making the designed product using the available processes and meeting the limitations imposed by budget constraints. Several feedback cycles between product design and process design usually take place before finalization of a product design that meets the needs of the customer and can also be manufactured in a feasible manner. A final test of product quality is its performance during usage by the customer. A robust product design encompasses a variety of environmental conditions with the objective of achieving a product performance that does not change drastically with a change in the operating conditions.

Quality management is a broad area. It is not feasible to deal with the general foundations and philosophies as well as operational details of implementation of the tools and techniques in one article. Therefore, an approach that shows the links between various components of a quality management system has been chosen. We provide a roadmap that starts with customer identification followed by prioritization of the needs of the

customer to create an appropriate product or provide a desired service. As meeting or exceeding customer needs is fundamental, the Kano model that incorporates the prioritized needs of the customer is presented. Basic quality management tenets associated with Juran, Crosby, and Deming are discussed. Further, the role of total quality management, a philosophy that holds the three components of the customer, process, and people together in a cohesive manner to create an organization that meets the desired quality objectives, is also presented.

At the strategic level, the impact of the various phases of adoption of a quality system on the organizational objectives is discussed. The components of quality costs are presented next, where the importance of quality in reducing total costs is demonstrated. We include this section as all levels of management understand the associated costs at their level and, further, they need to grasp the impact of quality improvement on total costs. With the twenty-first century global economy, a brief exposure to the processes of certification in quality management using global standards is important to multinational organizations or vendors that conduct business with organizations abroad. Hence, the role of the International Organization for Standardization (ISO) is briefly presented, followed by criteria for a national quality award in the United States, the Malcolm Baldrige Award.

HIERARCHICAL NEEDS OF THE CUSTOMER AND THEIR INFLUENCE ON QUALITY

A psychological theory of human needs proposed by Maslow [5] depicts a pyramidal structure of the various categories of needs. At the base lie physiological needs. Moving up the pyramid, we find the needs associated with safety, belonging, esteem, and self-actualization, respectively. Needs at the lower level have to be satisfied before those at the upper level are addressed. Similar to this concept, in the realm of quality, customer satisfaction is also influenced by certain types of needs [6]. The Kano model hypothesizes three prioritized categories of customer needs: basic needs, performance

needs, and excitement needs. Basic needs are those that are taken for granted by the customer—the customer expects such attributes to be present in a product. If they are missing, it will cause customer dissatisfaction and possible loss of market share. On the contrary, their presence may not necessarily increase market share. For example, a bearing must be able to withstand a certain minimal load. Meeting this requirement does not necessarily increase the satisfaction level of the customer; however, not meeting it will certainly cause dissatisfaction and possible loss of a customer.

The next category of performance needs consists of those that do influence the level of customer satisfaction, which normally changes linearly as a function of the level of the performance need. For instance, it might be desirable for the bearing to operate within a temperature range. Hence, if the bearing performs well at very high temperatures, customer satisfaction may increase linearly with the level of temperature under which it is able to adequately operate. Designing and manufacturing bearings that can function well at temperature extremes may well please the customer and improve market share. One strategic approach to retain and attract new customers could be through the satisfaction of performance needs, relative to that of the competitors' level of offering.

The third and most influential category is that of excitement needs. These are known as *delighters*. The customer sometimes may not even be aware of these before the purchase of the product. This category addresses those needs, if satisfied, will thrill the customer. For instance, the product has certain features that exceed the expectations of the customer. Customer satisfaction increases exponentially with the level of excitement needs. Identification of such needs and their incorporation into the design and manufacture of products is certainly an avenue to increase market share and leapfrog over competitors. For example, a certain ceramic material may increase the life of the bearing 10-fold over those produced by competitors. Further, it could be lighter in weight and may require minimal maintenance. The ability to manufacture such a bearing at a competitive cost

will have a tremendous impact on market share.

QUALITY MANAGEMENT PHILOSOPHIES

The principles of quality management apply to manufacturing and service industries. In a manufacturing industry, it is imperative for the product to perform its intended function in a way that meets or exceeds customer expectations. This is accomplished by the product having desirable features and operating characteristics that surpass the needs of the customer. Similarly, there are some quality characteristics that are unique to the service industry, distinct from those in manufacturing that must be met in order to achieve high customer satisfaction.

The delivery of service involves an interaction between the provider and the recipient. Thus, behavioral characteristics and human factors come into play. The courtesy and caring attitude of a nurse impacts patient satisfaction. Timeliness in providing the service is often of importance to the customer. Waiting time in a bank before a transaction or the waiting time to receive bags at an airport has an impact on customer satisfaction. A third type of quality characteristic involves service nonconformity. For example, the number of billing errors per 1000 accounts by a utility company is a measure of service quality. Finally, a fourth category consists of facility-related characteristics. Lack of a swimming pool in a hotel or insufficient legroom in an aircraft is an example.

All of the quality management philosophies strive for continuous quality improvement—a never-ending process. Top management commitment is also a common thread in these philosophies. Without adoption by senior management and support through resource allocation, any of the proposed approaches will fail after a short time span. Finally, quality must be a measurable entity. What cannot be measured is hard to monitor.

Philip B. Crosby's [1] approach utilizes a quality management grid that consists of five stages of maturity of the firm and six

measurement categories that aid in the evaluation of the degree of maturity in the utilization of the quality management philosophy. The stages of maturity are uncertainty, awakening, enlightenment, wisdom, and certainty. They represent the degree to which the principles of quality management are accepted in the organization. For example, in the uncertainty stage, there is no understanding of why problems occur, nor is there a comprehensive approach to prevent problems from happening. On the contrary, in the certainty stage, quality management is an integral part of the organizational culture and the focus is on prevention of problems. Similarly, the measurement categories pertain to evaluation of a firm's maturity in quality management and may range from "management understanding and attitude" to "quality organization status" to "problem handling" to "cost of quality as a percentage of sales" to "quality improvement actions" to "summary of company quality posture." For an organization that is in a stage of "uncertainty," an understanding of the use of quality as a management tool does not exist in the measurement category of "management understanding and attitude." Crosby also proposes a 14-step plan for quality improvement.

Joseph M. Juran's [2] approach consists of a quality trilogy involving quality planning, quality control, and quality improvement. At the upper management level, quality planning consists of establishing quality goals, whereas at the middle management level, it may involve setting departmental goals that are consistent with the strategic goals set by top management. Finally, at the operational level, planning may include workforce assignment and individual goal setting. The quality control phase deals with process control to determine sporadic causes of nonconformities. Remedial actions are identified in this phase. In the quality improvement phase, steps are taken to accomplish continuous improvement of the product and the process. Such actions may deal with chronic nonconformities and deficiencies that are part of the existing product or process.

W. Edwards Deming's [7] philosophy stresses the importance of the role of management. His belief was that over 85%

of the problems are due to *common causes* of variation, those that are inherent to the system and, therefore, can be addressed by management only. Alternatively, only 15% or less of the problems are due to *special causes*, those that are external to the system and can be dealt with by engineering and operating personnel.

Deming's approach is unique in several ways. It is one of the few that emphasizes a data-driven action plan. While experience and intuition are good attributes in decision-making, Deming stressed the importance of a *plan-do-check-act* (PDCA) cycle. Hence, data collected from the process based on a proposed improvement plan should be analyzed to validate its suggested effectiveness. In the event that results from data analysis do not confirm predicted expectations, one may have to revert to the planning stage in the PDCA cycle. Deming was one of the first pioneers in quality management to focus on a statistical approach. His methodology relies heavily on the use of control charts using a statistical process control (SPC) approach. A major objective of SPC is the identification of special causes in a timely manner. This enables the adoption of appropriate remedial actions to bring a process to a state of statistical control. Deming also believed in utilizing data to create knowledge. Data by itself is not sufficient to draw meaningful conclusions. On the other hand, when the available data is analyzed to create predictions based on selected hypotheses, it becomes a powerful tool. Deming was keenly aware of the importance of psychology as managing people necessitate an understanding of the behavior and interactions of people with others. He realized the importance of education and training for all. Further, he recognized the presence of barriers in the organization that prevent the flow of information. These barriers exist within departments, between departments, and between the organization and vendors and investors. Deming is credited with the concept of the "*extended process*," which recognizes that organizations need to consider vendors, customers, investors, employees, and the community in their decision-making process. Thus, in product design, a dynamic

link needs to exist between the organization and its vendors that supply raw material, parts, and components so as to come up with a feasible design. Deming's concept of *optimization of the system* utilizes the above idea with the objective to create a win-win situation for all.

The total quality management philosophy accomplishes the organizational goals through the integration of three entities—customer, process, and people (Fig. 1).

The achievement of quality in products/services is fundamental, as the degree of customer satisfaction is a function of the difference between quality expectations and that experienced. Customer expectations may be influenced by the external environment (or competitors) and are not solely impacted by the organization. However, the satisfaction level experienced by the customer is directly influenced by the level of quality of the products/services, which is under the control of the organization.

The second entity, critical to achievement of quality, is the process itself. In the manufacturing environment, this consists of, for example, the machinery and equipment, procedures and operations, line and staff people and their degree of expertise, suppliers and vendors, and the degree of product servicing. The philosophy of "continuous improvement" is the key to sustaining and maintaining a competitive edge, as customer needs and competition encountered are dynamic. In order to ensure an effective and efficient process, the concept of an "extended process," as advocated by Deming [7] is relevant. By including the customer in the extended process, it provides the company better opportunities to determine needs of the customer through consumer research and thereby develop appropriate strategies to satisfy and surpass customer expectations. Similarly, keeping the vendors as part of the team that recommends requisite product/process changes helps in creating a more effective process that produces a finished product with the desired characteristics.

The third entity in the total quality management model involves the people. Production of a quality product requires a motivated workforce. Empowering people so that

Figure 1. Features of a TQM model. [Source: Reprinted with permission from Ref. 4. Copyright 2008 Wiley & Sons.]

they may be involved in decision-making leads to creating a group that takes pride in its work skill. Through the promotion of open channels of communication, where management demonstrates its receptiveness to improvement ideas, a unified and encompassing approach to quality improvement is accomplished. All of this leads to the creation of a “quality culture” that permeates the organization.

IMPACT OF QUALITY ON ORGANIZATIONAL OBJECTIVES

The creation, delivery, and servicing of a quality product to the customer involves three phases, with feedback and interactions taking place among them. These are quality of design, quality of conformance, and quality of performance. Under quality of design, it must be ensured that the product meets the needs of the customer and is cost-effective

as well. Typically, the product is designed to at least exceed the customer needs using a safety factor. In the service sector, deciding on the means and procedures through which service will be provided is considered in the design phase. Quality of conformance addresses the issue of manufacturability or the providing of the service as planned. It must be feasible to produce what was designed at a cost-competitive rate. Alternatively, in the context of the service sector, it must be feasible to implement the procedures for rendering services, adopted in the design phase. Hence, feedback may take place between the phases of design and conformance. Quality of performance deals with the degree of satisfaction of the customer, when the product is used or when associated servicing on the product is conducted. In the service sector, it measures the degree to which the customer is satisfied on receiving the service. Thus, there may be feedback

from the performance to the design phase in the event that the product does not function accordingly, or if the service provided does not meet customer expectations.

QUALITY COSTS

Quality costs, in general, may be grouped into the four categories of prevention, appraisal, internal failure, and external failure [8]. In the category of prevention, are the costs associated with planning, implementing, and maintaining a quality system that includes product and process design. During the initial stage of implementation of a quality system, while prevention costs may increase, with the degree of quality improvement, the reductions in internal and external failure costs may more than off-set such increases leading to a reduction in total quality costs. Measuring and evaluating products, components, and raw materials to determine their degree of conformance to some specified standards falls in the category of appraisal costs. When products and components fail to meet established requirements, before being sold to the customer, the incurred costs are in the internal failure category. Costs of rework and scrap are examples. Lastly, when products do not function satisfactorily once sold to the customer, the costs incurred to handle complaints, warranty obligations, and product liability fall under external failure.

In general, as the level of quality increases, an increase may take place in the combined prevention and appraisal costs (Fig. 2). Associated with this increase in the level of quality, an exponential decline is usually encountered in the combined internal and external failure costs. Using a dynamic concept of the impact of quality improvement, beyond a certain level of quality, the shape of the prevention and appraisal function may change from a concave to a convex function. Hence, with further improvement in the quality level, and the continuing exponential decline in the internal and external cost functions, the total cost function may diminish. Thus, with the objective of minimizing the total cost function, the target becomes the achievement of a 100% level of conformance.

INTERNATIONAL STANDARDS ISO 9000

With manufacturing and service organizations becoming global in nature, a need exists for ensuring standardization in quality management systems across countries. The *International Organization for Standardization (ISO) 9000* [9] developed a system of quality management standards. These standards were first published in 1987 and were based on *BS 5750*, a series of standards developed by the British Standards Institute (BSI). The 1987 version had three models: ISO 9001: Model for quality assurance in design, development, production, installation, and servicing, which applied to organizations creating new products; ISO 9002: Model for quality assurance in production, installation, and servicing, which was similar to ISO 9001 but without the creation of new products; and ISO 9003: Model for quality assurance in final inspection and test, which dealt with inspection of the finished product only.

A revision of the ISO 9000 standards occurred in 1994. They emphasized quality assurance via prevention as opposed to just final inspection. The next revision took place in 2000 and integrated some key concepts in the standards. First, process management was at the heart of the standards, which included involvement of top management and system optimization, two concepts previously discussed. Second, the importance of process performance metrics was delineated, as continual process improvement could be monitored through such metrics. Third, customer satisfaction as the key objective was made explicit. The standards were revised again in 2008. This version only introduced clarifications to the 2000 version and added no new requirements.

Studies have investigated the impact of ISO 9001 certification on the business performance, financial performance, and process effectiveness of organizations [10–13]. While it is difficult to identify exact association between certification and profitability, there are some general advantages that may occur because of the process of certification. An effective and efficient process may be created through the satisfaction of the various requirements specified in the ISO standards.

Figure 2. Target level of 100% conformance. [Source: Reprinted with permission from Ref. 4. Copyright 2008 Wiley & Sons.]

This, in turn, may lead to increased customer satisfaction, improved market share, and increased profitability. Certification of vendors may lead to improved quality of material and components that are procured. In general, meeting the ISO standards may assist in making the organization competitive. Certification takes place through third party audits and has to be renewed according to a defined interval, currently once every three years.

There have been some criticisms of the ISO 9000 standards, one being the exorbitant amount of time and paperwork required in preparation for registration. Second, if the quality culture is not engrained in the organization, quality manuals and documentation created in the registration process may merely serve to meet the requirements of the standard without actually being used to improve quality in the operations. Third, the registration process may promote specification control without actually being used for process understanding and improvement.

ISO 9001 is a generic standard applicable to manufacturing and service industries. There are various other industry standards, as well as other ISO standards, that have been developed for specific industries. For example, in the United States, the *QS 9000* standards have been adopted by the automotive industry. An international automotive quality standard accepted in the United States and European automakers

is *ISO/TS 16949—Quality Systems: Automotive Suppliers*. The aerospace industry follows the standard *AS 9100: Quality Systems: Aerospace-Model for Quality Assurance in Design, Development, Production, Installation, and Servicing*. In the telecommunications service industry, the *TL 9000* standard is used. A few other industry specific ISO standards are shown in Table 1.

MALCOLM BALDRIGE NATIONAL QUALITY AWARD

In the United States, the strategic importance of quality management is formally recognized through the *Malcolm Baldrige National Quality Award* [14]. The award is monitored through the National Institute of Standards and Technology (NIST), an agency of the US Department of Commerce. The American Society for Quality (ASQ) administers the award program under contract to NIST.

A fundamental reason for the creation of the award is to motivate US companies to improve quality and productivity and become effective and efficient in their operations. The intention is to recognize industry and non-profit organizations that may serve as role models for others in their sector. Awards are given annually, and award winners are expected to disseminate their best practices to others in their field, with the objective that this will lead to adoption of

Table 1. Industry Specific ISO Standards

Standard Number	Application Area
ISO 9069	Information processing—standard generalized markup language
ISO/IEC 9126	Software engineering—product quality
ISO 9362	Banking—business identifier code
ISO 9564	Financial services—personal identification number management
ISO/IEC 9579	Information technology—remote database access
ISO 9992	Financial transaction cards—messages between the integrated circuit card and the card accepting device
ISO 10012	Measurement management systems
ISO 10218	Robots and robotic devices
ISO 10993	Biological evaluation of medical devices
ISO 13485	Medical devices
ISO 13628	Petroleum and natural gas industries
ISO 14001	Environmental management systems
ISO/TS 16949	Automotive production and relevant service part organizations
ISO 22000	Food safety management systems
ISO 26000	Guidance on social responsibility
ISO 31000	Risk management

Table 2. Malcolm Baldrige Award Criteria Categories for 2013–2014

Categories	Point Values
1. Leadership	120
1.1 Senior leadership	70
1.2 Governance and social responsibilities	50
2. Strategic planning	85
2.1 Strategy development	45
2.2 Strategy implementation	40
3. Customer focus	85
3.1 Voice of the customer	40
3.2 Customer engagement	45
4. Measurement, analysis, and knowledge management	90
4.1 Measurement, analysis, and improvement of organizational performance	45
4.2 Knowledge management, information, and information technology	45
5. Workforce focus	85
5.1 Workforce environment	40
5.2 Workforce engagement	45
6. Operations focus	85
6.1 Work processes	45
6.2 Operational effectiveness	40
7. Results	450
7.1 Product and process results	120
7.2 Customer-focused results	85
7.3 Workforce-focused results	85
7.4 Leadership and governance results	80
7.5 Financial and market results	80

improved quality management practices and, therefore, a rise in the general health of the industry. Awards are given in the following categories: *manufacturing*—companies or units that sell manufactured products or manufacturing processes, and producers of agricultural, mining, or construction products; *service*—companies or subunits that sell services; *small business*—companies or subunits that are engaged in manufacturing and/or provision of services that have 500 or fewer employees; *nonprofit or government organizations*; *education*—organizations that include elementary and secondary schools, colleges, universities, schools or colleges within universities, professional schools, community colleges, and technical schools; and *health care*—organizations include hospitals, health maintenance organizations (HMOs), health care facilities, and home health agencies.

The award criteria are built on the core values [14] of visionary leadership, customer-driven excellence, organizational and personal learning, valuing employees and partners, agility, focus on the future, managing for innovation, operational effectiveness, social media and social responsibility, focus on results and creating value, and a systems perspective. A detailed list of award criteria categories, subcategories, and point values for the *2013–2014 Criteria for Performance Excellence* in the manufacturing, service, small business, nonprofit, and government categories is shown in Table 2.

In the United States, various States have their own awards for excellence in quality management. The majority of these awards are based on a format and criteria similar to the *Malcolm Baldrige National Quality Award*.

CONCLUSIONS

As tools and techniques of operational methods for achievement of quality have been omitted, we now mention some of the available methods and cite appropriate references. It should be noted that there are additional articles on quality control or SPC in Section 4.1.5 of the *Wiley Encyclopedia of Operations Research and Management Science* (2013).

An article on “Quality Design, Control, and Improvement” is also found in the *Wiley Encyclopedia* (2013).

In product design, identification of the prioritized needs of the customer is quite important. In this context, procedural steps outlined in a planning tool known as *quality function deployment* (QFD) is a possible approach [6, 15–17]. Designing a product that meets the needs of the customer may be accomplished through QFD. Following product design, parts design, and process design may also be accomplished through QFD. Subsequent applications of QFD could be in production planning, prototype testing, finished product testing, and after-sales troubleshooting.

To determine the prioritized customer needs, QFD utilizes a set of weights, typically on a 1–5 ordinal scale. As this is subjective in nature, a better approach could use the analytic hierarchy process (AHP) that determines relative weights based on pairwise comparisons [18]. AHP was initially used in a multicriteria decision-making environment where the decision maker is interested in satisfying multiple objectives and is able to come up with a prioritized ranking of the objectives. Consistency in the relative ranking of the objectives is achieved through a pairwise comparison approach.

The subject of SPC deals with the monitoring of processes through statistical methods using *control charts*. Two cause systems that abound in processes are *common* and *special* causes. Common causes are those that are inherent to the system, whereas special causes exist because of some changes in the process. A process is said to be in statistical control when only common causes prevail in the system. Two general categories of control charts exist—variables and attributes. A variable is a quality characteristic that is measurable on a numerical scale, for example, thickness or tensile strength of a part. In the category of attributes, the product or item is classified as conforming or nonconforming. Alternatively, the monitoring of the number of nonconformities or defects is another application of attribute charts. Details on SPC may be found in Section 4.1.5.3 of the *Encyclopedia*. Under

variables control charts, typical ones are for the mean and range ($\bar{X}$ and R), mean and standard deviation ($\bar{X}$ and s), individuals and moving range (I and MR), moving average (MA), and the exponentially weighted moving average ($EWMA$) charts [4, 19]. Similarly, for attributes, typical control charts are for the proportion nonconforming (p), the number nonconforming (np), number of nonconformities (c), or the number of nonconformities per unit (u) chart [4, 19].

A procedure that monitors the quality of outgoing product, when 100% inspection is not feasible, is that of acceptance sampling. A sample of items is chosen from a batch or lot, and a decision is made to accept or reject the lot on the basis of the information contained in the sample. The parameters of the sampling plan are the sample size (n) and the acceptance number (c), which represents the maximum number of nonconforming items that can be observed in the sample in order to accept the batch. These parameters are determined on the basis of certain stipulated conditions, such as the risk of rejecting a “good” lot or the risk of accepting a “bad” lot [4, 20].

Quality in a product is often achieved through product design. Most products consist of multiple components and/or subassemblies. Adequate operation of the product is influenced by the functioning of the components and subassemblies and by the configuration through which they constitute the product. The reliability of a product or system is the probability of the system functioning effectively for a certain period of time under stated environmental conditions. The interested reader may refer to the article [16] in the Encyclopedia for an overview. Additional details on reliability computations for complex systems, procedures for analyzing the criticality of various failure modes, reliability testing sampling plans, accelerated testing, and design of experiments (DOEs) to assess reliability may be found in the following references [4, 21–23]. While the above references are focused on reliability of physical systems, an approach for effective software development makes use of a capability maturity model (CMM) [24].

Often, it is of interest to determine optimum settings of process or product parameters that accomplish a desired objective. For example, one may wish to identify the optimum level of process parameters such as speed, feed, and depth of cut in a machining operation, as well as a product parameter indicating the type of alloy to use, so as to minimize surface roughness. As data needs to be collected under various parameter settings, the topic of DOEs indicates a framework under which experimental runs are to be conducted. Further, statistical techniques exist to analyze the data to determine the influential factors and their settings [25]. Typically, methods of analysis of variance are used.

Some operational methods for quality improvement that describe procedures and related tools and techniques within the procedure are also found in the literature. Among these are the Six-Sigma approach and the Lean Six-Sigma approach developed in the industry as practical guides. Six Sigma may be viewed as a philosophy, methodology for continuous improvement, or as a metric of performance [4, 26, 27]. As an operational procedure, the Six-Sigma approach utilizes the *Define, Measure, Analyze, Improve, and Control* (DMAIC) methodology, details of which may be found in the references.

To summarize, we have provided a strategic overview of quality management. This includes customer identification along with their prioritized needs, some philosophies of quality management, and the impact of quality on an organization’s objectives that include cost minimization. A brief exposure to certification in ISO 9001 standards is contained along with guidelines for the Malcolm Baldrige National Quality Award in the United States.

QUANTUM COMMAND AND CONTROL THEORY

STEVE FORSYTHE
Applied Physics Laboratory-Precision
Engagement, Johns Hopkins
University, Dayton, Ohio

INTRODUCTION

Many military activities have an underlying theoretic body of knowledge. The search theory, for example, provides a basis for algorithms and situations involving searching, such as locating an enemy sub or trying to find a downed pilot. A theoretical foundation serves many useful purposes by enabling analysts to discuss and analyze the problem in a mathematical way. Competing methods can be evaluated on the basis of the theory to identify the relative merits of each. Command and Control (C2) is a critical military activity that has to date not been adequately described by an underlying computational theory. One of the more successful models for C2 is the Find, Fix, Track, Target, Engage, and Assess (F2T2EA) model. The limitation of this model is that it is not general enough: it assumes that there is a target to be engaged. This article presents a more generalized C2 model that focuses on the selection of a course of action (COA) by the commander.

When a military organization has a mission, it must decide how to carry out that mission. The commander's staff generates several different COAs (i.e., possible plans) and evaluates them based on some methodology. The results of these comparisons are presented to the commander so that the best COA can be selected. A common approach defined in the joint doctrine is the weighted numerical comparison method. This method for COA selection involves constructing a matrix with criteria to evaluate each COA against. Figure 1 shows a typical COA

decision matrix. COAs for this example are conventional ballistic missile (CBM), B-2 (bomber aircraft), and tomahawk land attack missile (TLAM). The criteria for the evaluation are listed on the left. Each COA is scored against each criterion and then the score is multiplied by a weight to get the weighted results. The weighted results are then summed and the highest sum is presumed to be the best COA. This approach has several limitations. What are the best criteria? How are appropriate weights chosen? Is the expected value really the best statistic to use? Other, more complex methods exist that overcome some of these limitations. Parnell [1] describes methods for dealing with uncertainty about the alternative scores as well as uncertainty about the weights. The Quantum C2 approach is being evaluated at the Johns Hopkins University Applied Physics Laboratory [2]. This simpler approach has the potential of being more easily adapted to military command and control problems. It is called Quantum C2 because, in Physics, the quantum theory takes objects that were formerly considered point masses and describes them using a probability distribution. Likewise, a key aspect of Quantum C2 is to describe a COA, not as a point estimate, but rather, as a probability distribution in the possible future outcome space.

Note that the assessments of the COAs in Fig. 1 are point estimates. These are the expected values but there is no insight into the extremes. In addition, Fig. 1 assumes that the results are all independent. In reality, if the attack misses the target, the risk of collateral damage goes way up and the probability of kill goes way down. A revised method is needed that takes these issues into account.

BACKGROUND

Military models of C2 take on many forms, each with particular strengths and weaknesses. With the revolution in commu-

COA Selection Decision Matrix							
Criteria	Weight	CBM	B-2	TLAM	Weighted Results		
					CBM	B-2	TLAM
Pd	20	0.6	0.9	0.8	20	60	40
Execution time	20	36	128	300	60	40	20
Collateral damage	20	Low	High	Medium	60	20	40
Fratricide risk	20	Low	Medium	Medium	60	40	40
Economy of force (risk to our forces)	20	Low	Medium	Low	60	40	60
Anti-access (ability to defeat)	20	High	High	Medium	60	60	40
Threats (against this option)	20	Low	Medium	Medium	60	40	40
Total					380	300	280
Recalculate							

Figure 1. Example of a COA selection matrix.

nications fueled by the Internet, new C2 paradigms have been proposed (e.g., net-centric), which propose a significantly different perspective on the organization and function of facilities. Current military missions typically require the participation of allies and nongovernment organizations (NGOs). This complex environment makes it challenging to choose the best COA. A model of C2 should be helpful in developing a methodology for COA selection.

Numerous conceptual models of C2 exist, such as John Boyd's OODA (observe, orient, decide, act) loop. This model was developed to explain fighter aircraft engagements but has been applied to a wide range of situations. Similar models include MAPE (monitor, access, plan, execute), SDA (sense, decide, act), and MAAPPER (monitor, access, analyze, predict, plan, execute, report) [3]. There is also the Lawson C2 model as well as the enterprise theory of C2 [4].

A representation of the OODA loop is shown in Fig. 2.

Other approaches such as Builder's Command Concepts focus on the art of command, suggesting that the essential communications up and down the chain of command can (and should) be limited to disseminating,

verifying, or modifying command concepts [5]. The ideal command concept is one that is so prescient, sound, and fully conveyed to subordinates that it would allow the commander to leave the battlefield before the battle commences, with no adverse effect upon the outcome [4].

THE C2 PROBLEM

The Department of Defense defines C2 as "The exercise of authority and direction by a properly designated commander over assigned and attached forces in the accomplishment of the mission. C2 functions are performed through an arrangement of personnel, equipment, communications, facilities, and procedures employed by a commander in planning, directing, coordinating, and controlling forces and operations in the accomplishment of the mission" [6]. For the purposes of this article, we adopt a slightly broader definition of C2, which encompasses both military and civil organizations. We shall define C2 as an allocation of resources by a leader over a set of opportunities to achieve a set of objectives while managing risks. The solution to the C2 problem is a

Figure 2. Representation of the OODA loop.

COA and the commander's challenge is to choose the best COA.

The C2 problem, then, addresses

1. how to define the set of opportunities,
2. how to best allocate resources among the opportunities, and
3. how best to carry out those decisions.

In order to analyze how a leader allocates resources over a set of opportunities, we must consider a plethora of different factors. These factors relate to the following:

1. *Desired outcomes*: the objectives we are trying to achieve.
2. *Unwanted outcomes*: those effects that we are trying to avoid or minimize.

Usually, there is a trade-off to be made between achieving the desired outcomes and avoiding unwanted outcomes. The classic example is to neutralize a military facility but not to harm the hospital nearby. With the currently available precision weapons, airstrikes have an excellent chance of destroying a target with minimal collateral damage, unlike in WWII, when bombing campaigns caused massive collateral damage because there were no other options. Numerous issues relate to the commander's

willingness to accept a higher risk of negative effects in order to achieve a greater likelihood of mission success. This trade-off between mission success and risk is the key to C2 and the art of command. The science of C2 is to use modern capabilities to inform the commander of the best set of options that span the mission success versus risk tradespace, so that the commander can apply his training and experience in selecting the best option from a set of good alternatives [7,8].

Figure 3 illustrates the key functions of the C2 process. In this figure, we define the boundary of the C2 process as the information interface with the rest of the world. Information flows in and the C2 system evaluates the information, selects opportunities to pursue, assigns and schedules resources against those opportunities, and then generates orders and other communications to execute the plan.

COA SELECTION

One of the reasons that military decision making is so challenging is that there is always a trade-off between possible unwanted outcomes (casualties and collateral damage) and achieving the desired outcomes of the mission objectives. It is clearly the commander's prerogative to make

Figure 3. The C2 problem. The cloud represents the things outside the C2 system; Φ , the set of information received by the commander (and staff); M, “Machine” that takes Φ as an input and produces Ω ; Ω , the set of opportunities that resources may be assigned against; S, “Machine” that takes Ω as input and produces orders; Orders, the set of communication that indicates the course of action (COA) selected.

Figure 4. The efficient frontier. A–D represent solutions on the efficient frontier. Each represents the maximum chance of success for a given level of risk. Solution E is dominated by solutions B and C. For the same level of success, B offers lower risk than E, while C offers greater rewards for the same level of risk as E.

this risk versus reward trade-off in choosing the best COA (Fig. 4). Assuming that the commander does not quantify the explicit trade-off (very unlikely) ahead of time, the C2 problem becomes a multiple objective optimization problem.

In situations where there are multiple criteria to optimize, one optimal solution does not exist; there is an efficient frontier of solutions. These solutions maximize the chance of success for a given amount of risk. Other solutions, which do not lie on the efficient frontier, are said to be dominated solutions

as they are strictly inferior to one or more other solutions.

How does one measure risk and reward for military situations? For each of these measures, a utility (or value) function is created, which assigns each solution a value based on the probability of negative outcomes or positive outcomes happening. Casualties and loss of assets are clearly negative outcomes that a commander would like to minimize, while positive outcomes are the accomplishment of various mission objectives.

FACTORS FOR DESIRED OUTCOMES AND UNWANTED OUTCOMES

Figure 5 presents an example of the factors that could be used to calculate a COA's rating for desired outcomes and unwanted outcomes [9,10]. The mission objectives define the desired outcomes and are usually stated in the commander's intent. Also, rules of engagement and constraints on operations are defined by the commander and these define the unwanted outcomes that the commander wants to minimize while maximizing the desired outcomes.

Figure 6 illustrates the two-dimensional COA outcome space. Ideally, a commander would like to accomplish the desired outcomes with few losses, low collateral damage, and so on. Therefore, the lower right quadrant is preferred since most or all of the desired outcomes are achieved with few, if any, unwanted outcomes. The upper left quadrant represents the worst possible outcomes: failing to accomplish the mission yet suffering significant unwanted outcomes. The upper right represents a victory but at

Figure 5. Subobjectives for desired outcomes and unwanted outcomes.

Figure 6. Two-dimensional COA outcome space.

a high cost. This is the very definition of a Pyrrhic victory. An example of a COA that is likely to fall into this quadrant would be the urban bombing campaigns of WWII. With the weapons of the day, there was no way to destroy the war-making capabilities of the enemy without significant collateral damage. The lower left quadrant represents reduced effectiveness but also low risk. An example might be the air campaign prior to ground combat in Desert Storm. Bombing was generally carried out from high altitude so as to minimize attrition, even though

this reduced the effectiveness of any given sortie. The mission requirements were such that moderate effectiveness at low risk was preferred to higher effectiveness at medium risk.

Any given COA has some probability of being in any of these quadrants. Figure 7 shows a probability distribution mapped to the two-dimensional COA outcome space.

Note that the distribution need not be unimodal. Figure 7 shows a bimodal distribution. The most likely result is to achieve most of the desired results with

Figure 7. Probability distribution in the two-dimensional COA outcome space.

Figure 8. Example probability distribution in the two-dimensional COA outcome space.

some unwanted outcomes. The results in the upper left indicate that there is also some likelihood of achieving only a few of the desired outcomes while suffering significant unwanted outcomes.

In the case of attacking a single target, where the desired outcome is the percentage of the target and the unwanted outcome is collateral damage, the two-dimensional probability outcome space might look like Fig. 8.

Combat simulations often have bimodal distributions where some key early event causes the results to shift from one combatant to the other. It is this type of unusual distribution that makes treating the COA as a probability distribution so important. Just estimating the mean of these values does not convey enough information.

HOW TO EVALUATE COAs

There are several ways that the probability distribution can be used in COA selection. Depending on the commander's comfort with quantitative methods, different methods are available ranging from simple (but still very useful) to more complex. This approach allows a commander to choose the most appropriate approach for a given mission,

thus maximizing the use of the science of C2 in support of the commander's art of C2.

A commander specifies information such as the maximum risk rules of engagement and minimum conditions for success in the commander's intent. This information can be combined with a probability distribution such as the one shown in Fig. 9 to define

Figure 9. Method 1 for defining the acceptable outcome space.

the acceptable region. One measure of the desirability of a COA is the probability that the COA will have a satisfactory outcome. In many ways, this is the key question that drives a COA selection.

The shaded region in Fig. 9 is the acceptable outcome space. The probability that this COA will result in an acceptable set of outcomes is equal to the percentage of the distribution that lies within the shaded region. Other COAs would have different distributions and so each COA could be evaluated on the basis of the probability of achieving a set of acceptable outcomes.

One limitation to Method 1 is that a commander might be willing to have higher unwanted outcomes if the desired outcomes are achieved. Method 2 begins by asking the commander to refine his statements on risk. What are the maximum unwanted outcomes that are acceptable given minimum acceptable desired outcomes? What are the maximum unwanted outcomes that are acceptable given total success in all desired outcomes?

If a commander has numerous subobjectives for desired outcomes and unwanted outcomes and does not want to use a utility function to combine them into the two-dimensional decision space, an alternative method would be to define an n -dimensional acceptable region where there are n subobjectives. Each COA would have a probability of achieving a result that satisfied all n of the subobjectives. The advantage of this approach is that it avoids the subjective weights of the utility functions. The disadvantage of this approach is that it treats all outcomes in a binary fashion: all acceptable results are equally good and all unacceptable results are equally bad. This n -dimensional method also does not provide the commander with a risk versus mission success trade-off.

Figure 10 shows how the shape of the desired outcome space is modified on the basis of this information. It also clearly shows that a trade-off exists between the desired outcomes and the unwanted outcomes.

Military decision makers often use green/yellow/red connotations to quickly convey information. Method 3 defines the

Figure 10. Method 2 for defining the acceptable outcome space.

acceptable outcome space as “green” and a portion of the outcome space could also be defined as “red.” This red space could be thought of as denoting disastrous results or other such descriptions based on the commander’s intent. A “Hail Mary” play in football, for example, has a high probability of getting a great result but it also has a high probability of being intercepted. It tends to be an all-or-nothing choice. Other strategies might have a lower chance of getting an acceptable outcome (getting a first down) but they avoid the disastrous results of a turnover. Using a green/red space such as that displayed in Fig. 11 would allow a commander to compare the likelihood of achieving acceptable results versus the likelihood of the results being extremely bad.

An n -dimensional approach can be taken with this method as well. The n subobjectives would have a range of “green” values that are acceptable, and each objective could have a “red” range of values that the commander wants to avoid at all costs. In this method, each COA would be evaluated to calculate the probability of it achieving an outcome where all the subobjectives are green as well as the probability that any of the subobjectives are red. The COAs could then be graphed on an x - y plot with the x values being the

Figure 11. Method 3 for defining the acceptable outcome space.

probability of green outcome and the y values being the probability of a red outcome. Once again, the commander could then make a risk versus mission success trade-off.

Figure 12 shows how the results of using the third method could be displayed for a commander. The COAs are plotted on an xy plot with the x axis being the probability that the outcome will have a green result for all criteria. The y axis is the probability that the outcome will have a result where one or more criteria are red. Once again, the commander is given a trade-off between increasing the likelihood of mission success (all green) versus risk (any red results).

A fourth and final method can be used if the commander or his staff can define a set of relative values for each part of the outcome space. Such a set of relative values (called *utility values*) represents how much the commander values achieving the specified outcomes. Figure 13 shows a notional set of values with the best possible outcome being valued 1000 and the worst possible valued at zero. A simple polynomial surface can be fit to a set of values to allow extrapolation between the points. The probability distribution of each COA is then scored against the utility values of the commander.

Figure 14 shows how the expected utility value for each COA is calculated. By

Figure 12. Methodology number three: mission success versus risk trade-off.

Figure 13. Commander's utility values.

applying values to each possible outcome, this method uniquely values each possible outcome. This utility theory method captures the commander's concern for unwanted outcomes as well as the importance of achieving the mission. This method has the most stringent requirements for data: utility values that the commander has confidence in. By using the utility data, the method allows for the calculation of the highest expected utility. This method therefore takes into account the

Figure 14. Calculating expected utility value for two COAs.

entire probability distribution and the commander's utility for outcomes associated with all parts of the outcome space.

CONCLUSION

This article provides a new approach to C2 COA selection, which has the potential to be an improvement on the current COA selection methodologies. The Quantum C2 theory treats the COA as a probability distribution that needs to be evaluated to determine the best COA based on the commander's guidance. Four methodologies are discussed, each of which offers some potential advantages over the current COA evaluation methodologies. The simplest method requires only knowledge of the minimum acceptable desired outcomes and unwanted outcomes. The most sophisticated approach uses utility theory to calculate the COA with the maximum expected utility. Thus, the Quantum C2 approach can accommodate different commanders with different approaches to COA evaluation.

QUANTUM GAME THEORY

STEVEN E. LANDSBURG
Department of Economics,
University of Rochester,
Rochester, New York

Quantum game theory is the study of strategic behavior by agents with access to quantum technology. Broadly speaking, this technology can be employed in either of two ways: as part of a randomization device or as part of a communications protocol.

When it is used for randomization, quantum technology allows players to coordinate their strategies in certain ways. The equilibria that result are all correlated equilibria in the sense of Aumann [1], but they form a particularly interesting subclass of correlated equilibria, namely, those that are both achievable and deviation-proof when players have access to certain naturally defined technologies. Not all correlated equilibria can be implemented via quantum strategies, and of those that can, not all are quantum-deviation-proof.

When players have access to private information, the theories of correlated and quantum equilibrium diverge still further, with the classical equivalence between mixed and behavioral strategies breaking down, and the appearance of new equilibria that have no classical counterparts.

The second game theoretic application of quantum technology, other than randomization, is to communication. This leads to a new set of equilibria that seem to have no natural interpretation in terms of correlated equilibria or any other classical concepts.

In the first section, we review the elements of game theory, with special emphasis on those aspects that are generalized or modified by quantum phenomena. In the second section, we survey games with quantum randomization and in the third section, we survey games with quantum communication.

GAME THEORY

Games

A *two-person game* consists of two sets S_1 and S_2 and two maps

$$P_1 : S_1 \times S_2 \rightarrow \mathbf{R} \text{ and } P_2 : S_1 \times S_2 \rightarrow \mathbf{R},$$

where $\mathbf{R}$ denotes the real numbers. The sets S_i are called *strategy sets* and the functions P_i are called *payoff functions*. Games are intended to model strategic interactions between agents who are usually called *players* (though the players are not part of this formal definition). The value $P_i(x, y)$ is called the *payoff* to Player i when Player 1 chooses strategy x and Player 2 chooses strategy y .

For simplicity, we will usually assume the sets S_i are finite.

A *solution concept* is a function that associates to each game a subset of $S_1 \times S_2$; the idea is to pick out those pairs of strategies that we believe players might select in real-world situations modeled by the game. The appropriate solution concept depends on the intended application. The most studied solution concept is the *Nash equilibrium*. A pair (x, y) is called a Nash equilibrium if x maximizes the function $P_1(-, y)$ and y maximizes the function $P_2(x, -)$.

Mixed Strategies

To provide an accurate model of real-world strategic situations, we must allow for the possibility that players might bend the rules. For example, instead of choosing a single strategy, one or both players might randomize. Starting with a game $\mathbf{G}$, we model this possibility by constructing the *associated mixed strategy game* $\mathbf{G}^{\text{mixed}}$ in which the strategy space S_i is replaced with the set $\Omega(S_i)$ of probability distributions on S_i , and the payoff function P_i is replaced with the function

$$P_i^{\text{mixed}} : (\mu, \nu) \mapsto \int P_i(x, y) d\mu(x) d\nu(y)$$

Although $\mathbf{G}^{\text{mixed}}$ is not the same game as $\mathbf{G}$, it is traditional to refer to a Nash equilibrium in $\mathbf{G}^{\text{mixed}}$ as a *mixed strategy equilibrium* in the game $\mathbf{G}$.

An alternative but equivalent model would allow Player i to choose, not a probability distribution on S_i but an S_i -valued random variable from some allowable set. This is the approach we will generalize in what follows.

Correlated Strategies

In the play of $\mathbf{G}^{\text{mixed}}$, we can imagine that Player i first selects a probability distribution, then selects a random variable (with values in S_i) that realizes that distribution, then observes a realization of that random variable, and then plays accordingly. Implicit in this description is that the random variables available to Player 1 are statistically independent of those available to Player 2.

In the real world, however, this is not always true. In the extreme case, both agents might be able to observe the *same* random variable—such as the price of wheat as reported in the *Wall Street Journal*. We can model this extreme case by replacing $\mathbf{G}$ with a set of games $\{\mathbf{G}_\alpha\}$, one for each value α of the jointly observed random variable. We then analyze each game $\mathbf{G}_\alpha$ separately.

But in less extreme cases, we need a new concept. An *environment* for $\mathbf{G}$ is a pair $(\mathcal{X}_1, \mathcal{X}_2)$, where $\mathcal{X}_i$ is a set of S_i -valued random variables. (We do not assume that random variables in $\mathcal{X}_1$ are necessarily independent of those in $\mathcal{X}_2$.) It is natural to assume that for any $X \in \mathcal{X}_i$ and any map $\sigma : S_i \rightarrow S_i$, the random variable $\sigma \circ X$ is also in $\mathcal{X}_i$. (This models the notion that players should be able to map realizations to strategies any way they want to.)

Given such an environment, we define a new game $\mathbf{G}(E) = \mathbf{G}(\mathcal{X}_1, \mathcal{X}_2)$ as follows:

Player i 's strategy set is $\mathcal{X}_i$. The payoff functions are defined in the obvious way, namely

$$P_i(X, Y) = \int_{S_1 \times S_2} P_i(x, y) d\mu_{X, Y}(x, y),$$

where $\mu_{X, Y}$ is the joint probability distribution on $S_1 \times S_2$ induced by (X, Y) .

Definition 1. The pair of random variables (X, Y) is called a *correlated equilibrium* in $\mathbf{G}$ if it is a Nash equilibrium in the game $\mathbf{G}(\{X\}, \{Y\})$. Two correlated equilibria are *equivalent* if they induce the same probability distribution on $S_1 \times S_2$. We will frequently abuse language by treating equivalent correlated equilibria as if they were identical.

It is easy to prove the following.

Proposition 1. *Let E be an environment and suppose that (X, Y) is a Nash equilibrium in the game $\mathbf{G}(E)$. Then (X, Y) is a correlated equilibrium in $\mathbf{G}$.*

However, the converse to Proposition 1 does not hold.

Example 1. Let $S_1 = S_2 = \{\mathbf{C}, \mathbf{D}\}$. Let X , Y , and W be random variables such that

$$\begin{aligned} \text{Prob}(X = W = \mathbf{C}) &= \text{Prob}(X = W = \mathbf{D}) = 1/8, \\ \text{Prob}(X \neq W = \mathbf{C}) &= \text{Prob}(X \neq W = \mathbf{D}) = 3/8, \\ \text{Prob}(Y = W = \mathbf{C}) &= \text{Prob}(Y = W = \mathbf{D}) = 1/12, \\ \text{Prob}(Y \neq W = \mathbf{C}) &= \text{Prob}(Y \neq W = \mathbf{D}) = 5/12. \end{aligned}$$

Let $E = (\{X, Y\}, \{W\})$. Let $\mathbf{G}$ be the game with the following payoffs:

		Player 2	
		C	D
Player 1	C	(0,0)	(2,1)
	D	(1,2)	(0,0)

It is easy to check that both (X, W) and (Y, W) yield correlated equilibria in $\mathbf{G}$. But (X, W) is not an equilibrium in the game $\mathbf{G}(E)$, though (Y, W) is.

Games with Private Information

In real-world strategic interactions, either player might know something the other does not. We model this situation as a *game of private information*, consisting of two strategy spaces S_i , two sets (called *information sets*) $\mathcal{A}_i$, a probability distribution on $\mathcal{A}_1 \times \mathcal{A}_2$, and two payoff functions

$$P_i : \mathcal{A}_1 \times \mathcal{A}_2 \times S_1 \times S_2 \rightarrow \mathbf{R}.$$

Given a game of private information, the *associated game* $\mathbf{G}^\#$ has strategy sets $S_i^\# = \text{Hom}(\mathcal{A}_i, S_i)$ and payoff functions

$$P_i^\#(F_1, F_2) = \int_{\mathcal{A}_1 \times \mathcal{A}_2} P_i(A_1, A_2, F_1(A_1), F_2(A_2)).$$

(Here $\text{Hom}(A, S)$ denotes the set of all functions from A to S .)

If $\mathbf{G}$ is a game of private information, a *Nash equilibrium* in $\mathbf{G}$ is (by definition) a Nash equilibrium in the ordinary game $\mathbf{G}^\#$.

Now we want to enrich the model so players can randomize. To this end, let E be an environment in the sense of the section titled “Correlated Strategies”; that is, $E = (\mathcal{X}_1, \mathcal{X}_2)$, where $\mathcal{X}_i$ is a set of S_i -valued random variables. We define the *associated environment* $E^\# = (\mathcal{X}_1, \mathcal{X}_2)$ by setting $\mathcal{X}_i^\# = \text{Hom}(\mathcal{A}_i, \mathcal{X}_i)$ and identifying the latter set with a set of $S_i^\#$ -valued random variables.

Thus, if $\mathbf{G}$ is a game of private information with environment E , we can first “eliminate the private information” by passing to the associated game $\mathbf{G}^\#$ and environment $E^\#$, and then “eliminate the random variables” by passing to the associated game $\mathbf{G}^\#(E^\#)$ as in the discussion preceding Definition 1. Now we are studying an ordinary game, where we have the ordinary notion of Nash equilibrium.

Unfortunately, *this construction does not generalize to the quantum context*. To get a construction that generalizes, we need to proceed in the opposite order, by first eliminating the random variables and then eliminating the private information:

Construction 1. Given a game of private information $\mathbf{G}$ with an environment

$E = (\mathcal{X}_1, \mathcal{X}_2)$, define a new game of private information $\mathbf{G}(E)$ as follows:

The information sets $\mathcal{A}_i$ and the probability distribution on $\mathcal{A}_1 \times \mathcal{A}_2$ are as in $\mathbf{G}$. The strategy sets are the $\mathcal{X}_i$. The payoff functions are

$$\begin{aligned} P_i(A_1, A_2, X, Y) \\ = \int_{S_1 \times S_2} P_i(A_1, A_2, s_1, s_2) d\mu_{X,Y(s_1, s_2)}. \end{aligned}$$

Now applying the $\#$ construction to $\mathbf{G}(E)$ gives an ordinary game $\mathbf{G}(E)^\#$.

Theorem 1. $\mathbf{G}(E)^\# = \mathbf{G}^\#(E^\#)$.

Remark. In spirit, and in the language of Kuhn [2], $\mathbf{G}^\#(E^\#)$ is like the associated game with *mixed strategies*, where Player i chooses a probability distribution over maps $\mathcal{A}_i \rightarrow S_i$, while $\mathbf{G}(E)^\#$ is like the associated game with *behavioral strategies*, where Player i chooses, for each element of $\mathcal{A}_i$, a probability distribution over S_i . In Kuhn [2], these games are equivalent in an appropriate sense; here they are actually the same game. The difference is that in Kuhn [2], players choose probability distributions, whereas here they choose random variables. But the two approaches are fundamentally equivalent.

Quantum Game Theory

The notions of mixed strategy and correlated equilibria are meant to model the real-world behavior of strategic agents who have access to randomizing technologies (such as weighted coins). *Quantum game theory* is the analogous attempt to model the behavior of strategic agents who have access to quantum technologies (such as entangled particles).

Broadly speaking, there players might use these quantum technologies in either of two ways: as randomizing devices or as communication devices. We will consider each in turn.

QUANTUM RANDOMIZATION

Quantum Strategies

Just as the theory of mixed strategies models the behavior of players with access to

classical randomizing devices, the theory of quantum strategies models the behavior of players with access to quantum randomizing devices. These devices provide players with access to families of observable quantities that cannot be modeled as classical random variables.

For example, let X, Y, Z and W be binary random variables. Classically we have the near triviality:

$$\begin{aligned} \text{Prob}(X \neq W) &\leq \text{Prob}(X \neq Y) \\ &+ \text{Prob}(Y \neq Z) + \text{Prob}(Z \neq W). \end{aligned}$$

Proof. Imagine X, Y, Z, W lined up in a row; in order for X to differ from W , at least one of X, Y, Z, W must differ from its neighbor.

But if X, Y, Z , and W are quantum mechanical measurements, this inequality need not hold. (The most obvious paradoxes are avoided by the fact that neither X and Z , nor Y and W , are simultaneously observable.)

To model the behavior of agents who can make such measurements, we can mimic the construction preceding Definition 1, replacing the sets $\mathcal{X}_i$ of random variables with sets $\mathcal{X}_i$ of quantum mechanical observables. We require that any $X \in \mathcal{X}_1$ and any $Y \in \mathcal{X}_2$ be simultaneously observable. We call such a pair $E = (\mathcal{X}_1, \mathcal{X}_2)$ a *quantum environment*. (Quantum environments will be defined more precisely in the section titled “The Quantum Environment” below.) Given such a quantum environment and given a game $\mathbf{G}$, we construct a new game $\mathbf{G}(E)$ just as in the discussion preceding Definition 1.

If (X, Y) is a Nash equilibrium in $\mathbf{G}(E)$, we sometimes speak loosely enough to say that (X, Y) is a *quantum equilibrium* in $\mathbf{G}$, though the property of being a quantum equilibrium depends not just on $\mathbf{G}$ but on the environment E . Two quantum equilibria are called *equivalent* if they induce the same probability distribution on $S_1 \times S_2$, and, as with correlated equilibria, we will sometimes speak of equivalent quantum equilibria as if they were identical.

If (X, Y) is a quantum equilibrium then (by the definition of quantum environment),

X and Y are simultaneously observable and hence can be treated as classical random variables. With this identification, it is easy to show that any quantum equilibrium is a correlated equilibrium. (This generalizes Proposition 1.) However, just as in Example 1, the converse need not hold. A pair (X, Y) that is an equilibrium in one quantum environment need not be an equilibrium in another.

The Quantum Environment

Consider a game in which the strategy sets are $S_1 = S_2 = \{\mathbf{C}, \mathbf{D}\}$. Players can implement (ordinary classical) mixed strategies by flipping (weighted) pennies, mapping the outcome “heads” to the strategy $\mathbf{C}$, and the outcome “tails” to the strategy $\mathbf{D}$.

While a classical penny occupies either the state $\mathbf{H}$ (heads up) or $\mathbf{T}$ (tails up), a quantum penny can occupy any state of the form $\psi = \alpha\mathbf{H} + \beta\mathbf{T}$, where α and β are complex scalars, not both zero. A heads/tails measurement of such a penny yields the outcome either $\mathbf{H}$ or $\mathbf{T}$ with probabilities proportional to $|\alpha|^2$ and $|\beta|^2$. Physical actions such as rotating the penny induce unitary transformations of the state space, so that the state ψ is replaced by $U\psi$ where U is some unitary operator on the complex vector space $\mathbf{C}^2$.

(Of course literal macroscopic pennies do not behave this way, but spin-1/2 particles such as electrons do, with “heads” and “tails” replaced by “spin up” and “spin down”.)

A single quantum penny is no more or less useful than a classical randomizing device. If you want to play heads with probability p , you can first apply a unitary transformation that converts the state to some $\gamma\mathbf{H} + \delta\mathbf{T}$ with $|\gamma|^2/(|\gamma|^2 + |\delta|^2) = p$, then measure the heads/tails state of the penny and play accordingly.

However, two players equipped with quantum pennies have something more than a classical randomizing device. A pair of quantum pennies occupies a state of the form

$$\alpha\mathbf{H} \otimes \mathbf{H} + \beta\mathbf{H} \otimes \mathbf{T} + \gamma\mathbf{T} \otimes \mathbf{H} + \delta\mathbf{T} \otimes \mathbf{T},$$

where $\alpha, \beta, \gamma, \delta$ are complex scalars, not all zero. A physical manipulation of the first penny transforms the first factor unitarily and a physical manipulation of the second

penny transforms the second factor unitarily. Subsequent measurements yield the outcomes (heads, heads), (heads, tails), and so forth with probabilities proportional to $|\alpha|^2$, $|\beta|^2$, and so forth. This allows the players to achieve joint probability distributions that cannot be achieved via the observations of independent random variables.

Example 2. Suppose that two pennies begin in the *maximally entangled state* $\mathbf{H} \otimes \mathbf{H} + \mathbf{T} \otimes \mathbf{T}$. Players 1 and 2 apply the transformations U and V to the first and second pennies where

$$U = \begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{pmatrix}$$

$$V = \begin{pmatrix} \cos(\phi) & \sin(\phi) \\ -\sin(\phi) & \cos(\phi) \end{pmatrix}$$

This converts the state from $\mathbf{H} \otimes \mathbf{H} + \mathbf{T} \otimes \mathbf{T}$ to

$$\begin{aligned} U\mathbf{H} \otimes V\mathbf{H} + U\mathbf{T} \otimes V\mathbf{T} &= \cos(\theta - \phi)\mathbf{H} \otimes \mathbf{H} \\ &+ \sin(\theta - \phi)\mathbf{H} \otimes \mathbf{T} - \sin(\theta - \phi)\mathbf{T} \otimes \mathbf{H} \\ &+ \cos(\theta - \phi)\mathbf{T} \otimes \mathbf{T}. \end{aligned}$$

If players map the outcomes $\mathbf{H}$ and $\mathbf{T}$ to the strategies $\mathbf{C}$ and $\mathbf{D}$, then the resulting probability distribution over strategy pairs is

$$\begin{aligned} \text{Prob}(\mathbf{C}, \mathbf{C}) &= \text{Prob}(\mathbf{D}, \mathbf{D}) = \cos^2(\theta - \phi)/2 \\ \text{Prob}(\mathbf{C}, \mathbf{D}) &= \text{Prob}(\mathbf{D}, \mathbf{C}) = \sin^2(\theta - \phi)/2. \end{aligned}$$

We can now make precise the notion of *quantum environment*; a quantum environment is a triple $(\xi, \mathcal{X}_1, \mathcal{X}_2)$ where

1. ξ is a nonzero vector in a complex vector space $\mathbf{C}^{n_1} \otimes \mathbf{C}^{n_2}$ (with n_1 and n_2 assumed finite here, though this could all be generalized)
2. $\mathcal{X}_i$ is a set of unitary operators on $\mathbf{C}^{n_i}$.

The unitary operators fill the same role as the sets of random variables in the section titled “Game Theory”; they are the things that players can observe, and on whose realizations they can condition their strategies.

Quantum Equilibrium

Consider again the game $\mathbf{G}$ from Example 1.

		Player 2	
		C	D
Player 1	C	(0,0)	(2,1)
	D	(1,2)	(0,0)

Let E be the following quantum environment: $\xi = \mathbf{H} \otimes \mathbf{H} + \mathbf{T} \otimes \mathbf{T}$, where $\{\mathbf{H}, \mathbf{T}\}$ is a basis for the complex vector space $\mathbf{C}^2$; $\mathcal{X}_1 = \mathcal{X}_2$ is the set of all operators that take the form

$$M(\theta) = \begin{pmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{pmatrix} \quad (1)$$

when expressed in terms of the basis $\{\mathbf{H}, \mathbf{T}\}$.

Physically, this means that each player has access to one member of a pair of maximally entangled pennies, and can rotate that penny through any angle before measuring its heads/tails orientation.

Taking Player 2’s angle ϕ as given, Player 1 clearly optimizes by choosing θ so that $\sin(\theta - \phi) = 1$, and symmetrically with the players reversed. Thus in equilibrium, the outcomes (2, 1) and (1, 2) are each realized with probability 1/2.

As we have noted earlier, this is of course a correlated equilibrium, but it is more than that. For example, the correlated equilibria (X, W) and (Y, W) of Example 1 are not sustainable as quantum equilibria in this environment.

Quantum Games of Private Information

Let $\mathbf{G}$ be a game of private information as defined in the section titled “Games with Private Information”, and let E be a quantum environment.

We would like to model the play of $\mathbf{G}$ in the environment E as the play of an ordinary game. A natural attempt is to replace $\mathbf{G}$ with the game $\mathbf{G}^\#$ defined in the section titled “Games with Private Information”; recall that a strategy in $\mathbf{G}^\#$ is a map from the information set $\mathcal{A}_i$ to the strategy set S_i .

However, in the quantum case there is no natural way to define an environment $E^\#$ for this game. More precisely, it is shown in Dahl and Landsburg [3] that the natural definition of $E^\#$ makes sense when and only when the measurements in $\mathcal{X}_1 \cup \mathcal{X}_2$ have a single joint probability distribution, so that they can be thought of as classical random variables. In other words, the existence of an environment $E^\#$ is equivalent to the absence of any specifically quantum phenomena.

Therefore, we must generalize not the construction $\mathbf{G}^\#(E^\#)$ from the section titled “Games with Private Information”, but the classically equivalent construction $\mathbf{G}(E)^\#$. In the language of Kuhn [2] (and of the remark at the end of the section titled “Games with Private Information”), quantum game theory allows players to choose behavioral strategies without equivalent mixed strategies.

Example 3 [This example is adapted from Cleve *et al.* [4]]. Let $\mathbf{G}$ be the following game of private information.

The information sets are $\mathcal{A}_1 = \mathcal{A}_2 = \{\text{red}, \text{green}\}$. The probability distribution on $\mathcal{A}_1 \times \mathcal{A}_2$ is uniform. The payoff functions are specified as follows:

If both players observe red

		Player Two	
		C	D
Player One	C	(1,1)	(0,0)
	D	(0,0)	(1,1)

If either player observes green

		Player Two	
		C	D
Player One	C	(0,0)	(1,1)
	D	(1,1)	(0,0)

The environment E is as in the paragraph preceding Equation (1).

In the game $\mathbf{G}(E)^\#$, players choose maps $\mathcal{A}_i \rightarrow \mathcal{X}_i$.

To find equilibria in this game, suppose that Player 1 has chosen to map “red” and “green” to $M(\theta_{\text{red}})$ and $M(\theta_{\text{green}})$, while Player 2 has chosen $M(\phi_{\text{red}})$ and $M(\phi_{\text{green}})$ (where the M matrices are as defined in Equation (1)). Then we can compute Player 1’s expected payoffs as functions on $\mathcal{A}_1 \times \mathcal{A}_2$:

$$EP_1(\text{red}, \text{red}) = \cos^2(\theta_{\text{red}} - \phi_{\text{red}}) \quad (2)$$

$$EP_1(\text{red}, \text{green}) = \sin^2(\theta_{\text{red}} - \phi_{\text{green}}) \quad (3)$$

$$EP_1(\text{green}, \text{red}) = \sin^2(\theta_{\text{green}} - \phi_{\text{red}}) \quad (4)$$

$$EP_1(\text{green}, \text{green}) = \sin^2(\theta_{\text{green}} - \phi_{\text{green}}). \quad (5)$$

Because the probability distribution on $\mathcal{A}_1 \times \mathcal{A}_2$ is uniform, Player 1 seeks to maximize the sum of these four expressions, taking ϕ_{red} and ϕ_{green} as given. At the same time (due to the symmetry of the problem) Player 2 seeks to maximize the identical sum, taking θ_{red} and θ_{green} as given.

Given this, we can compute that there are two types of equilibria:

1. Equilibria in which exactly three of the four expressions (2)–(5) are equal to 1 and the fourth is equal to 0. All four possibilities occur with $\phi_r, \phi_g, \theta_r, \theta_g \in \{0, \frac{\pi}{2}, \pi\}$. In these equilibria each player receives a payoff of $3/4 = 0.75$.
2. Equilibria equivalent to $\{\phi_{\text{red}} = 0, \phi_{\text{green}} = 3\pi/4, \theta_{\text{red}} = \pi/8, \theta_{\text{green}} = 3\pi/8\}$. In these equilibria each player receives a payoff of $(1/2 + \sqrt{2}/4) \approx 0.85$.

The best equilibrium that can be reached in any classical environment is equivalent to an equilibrium of type (1). This is so even when the classical environment includes correlated random variables.

For ordinary games, we observed that every quantum equilibrium is also a correlated equilibrium. For games of private information, this example demonstrates that no analogous statement is true.

QUANTUM COMMUNICATION

Communication

In any real-world implementation of a game, players must somehow communicate their strategies before they can receive payoffs. This follows from the fact that the payoff functions take both players' strategies as arguments; therefore, information about both strategies must somehow be present at the same place and time.

Ordinarily, the communication process is left unmodeled. But in this section, we need an explicit model so that we can explore the effects of allowing quantum communication technology. To that end we postulate a referee who communicates with the players by handing them markers (say pennies), which the players can transform from one state to another (say by flipping them over or leaving them unflipped) to indicated their strategy choices; the markers are eventually returned to the referee who examines them and computes payoffs.

Of course not all real-world games have literal referees; sometimes the players are firms, their strategies are prices, and the prices are communicated not to a referee but to a marketplace, where payoffs are "computed" via market processes. In the models to follow, the referee can be understood as a metaphor for such processes.

A Quantum Move

Consider the game with the following payoff matrix (for now, view the labels **NN**, **NF**, etc., as arbitrary labels for strategies):

		Player 2	
		N	F
Player 1	NN	(1,0)	(0,1)
	NF	(0,1)	(1,0)
	FN	(0,1)	(1,0)
	FF	(1,0)	(0,1)

As noted above, classical game theory does not ask how players communicate with the referee. If we want to embellish our model

with an explicit communication protocol, there are several essentially equivalent ways to do it.

The Simplest Protocol. The referee passes two pennies to Player 1, who flips both to indicate a play of **FF**, flips only the first to indicate a play of **FN**, and so forth, and one penny to Player 2, who flips (**F**) or does not (**N**). The pennies are returned to the referee, who examines their states and makes payoffs accordingly.

An Alternative Protocol. A single penny in state **H** is passed to Player 1, who either flips or does not; the penny is then passed to Player 2, who either flips or does not; the penny is then returned to the Player 1, who either flips or does not; the penny is then returned to the referee who makes payoffs of (1, 0) if the final state is **H** or (0, 1) if the final state is **T**. (The players are blindfolded and cannot observe each others' plays.)

We can set things up so that flipping and not flipping correspond to the applications of the unitary matrices

$$\mathbf{F} = \begin{pmatrix} 0 & 1 \\ -i & 0 \end{pmatrix}, \mathbf{N} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad (6)$$

Now suppose that Player 1 manages to cheat by employing arbitrary unitary operations. Under the simplest protocol, this is equivalent to playing a mixed strategy and gives Player 1 no advantage. But under the alternative protocol, Player 1 can guarantee himself a win by choosing the unitary matrix

$$U = \frac{1}{2} \begin{pmatrix} 1+i & \sqrt{2} \\ -\sqrt{2} & 1-i \end{pmatrix}$$

on his first turn and U^{-1} on his second. This guarantees him a win because $U^{-1} \circ \mathbf{F} \circ U$ and $U^{-1} \circ \mathbf{N} \circ U$ are both diagonal matrices, so that both fix the state **H**. (Recall that states are unchanged by scalar multiplication.) In other words, the final state is now **H** regardless of Player 2's strategy.

Note that it might be quite impossible to prohibit Player 1 from employing the matrix U , for exactly the same reason that it is usually quite impossible to prohibit players for

adopting mixed strategies: When the referee makes his final measurement, the only information revealed is the final state of the penny, not the process by which it achieved that state.

This example, due to Meyer [5], illustrates two points: First, quantum communication can matter. Second, whether or not quantum communication matters depends not just on the game $\mathbf{G}$; it depends on the specified communications protocol.

The Eisert–Wilkens–Lewenstein Protocol

The Eisert–Wilkens–Lewenstein protocol ([6,7]) captures the potential effects of quantum communication in a quite general context and is therefore the most studied protocol in games of quantum communication.

We start with a game $\mathbf{G}$ in which the strategy sets are $S_1 = S_2 = \{\mathbf{C}, \mathbf{D}\}$. (Everything can be generalized to larger strategy sets, but we will stick to this simplest case.) The referee prepares a pair of pennies in the state $\mathbf{H} \otimes \mathbf{H} + \mathbf{T} \otimes \mathbf{T}$, and passes one penny to each player, with Player 1 receiving the “left-hand” penny.

Players are instructed to play/operate with one of the unitary matrices $\mathbf{F}$ and $\mathbf{N}$ of Equation (6), with $\mathbf{F}$ indicating a desire to play $\mathbf{D}$ and $\mathbf{N}$ a desire to play $\mathbf{C}$. Players actually operate with the unitary matrices of their choices and then return the pennies to the referee, who makes a measurement that distinguishes among the four states that could result if the players followed instructions.

We can of course model this situation by saying that the original game $\mathbf{G}$ has been replaced by the *associated quantum game* $\mathbf{G}^Q$ (not to be confused with the associated quantum games that arise in the very different context of the section titled “Quantum Randomization”), with strategy sets equal to the unitary group U_2 (or, equivalently—because states are unchanged by scalar multiplication—the special unitary group SU_2) and payoff functions having the obvious definition. It is observed in Landsburg [8] that $\mathbf{G}^Q$ is equivalent to the following game:

- The strategy sets S_i^Q are both equal to the group of unit quaternions (which is

isomorphic to the special unitary group SU_2).

- The payoff functions are defined as follows:

$$P_i^Q(\mathbf{p}, \mathbf{q}) = A^2 P_i(\mathbf{C}, \mathbf{C}) + B^2 P_i(\mathbf{C}, \mathbf{D}) \\ + C^2 P_i(\mathbf{D}, \mathbf{C}) + D^2 P_i(\mathbf{D}, \mathbf{D}),$$

where P_i is the payoff function in $\mathbf{G}$ and where

$$\mathbf{pq} = A + Bi + Cj + Dk.$$

The group structure on the strategy sets guarantees that (except in the uninteresting case where both payoff functions are maximized at the same arguments) there can be no pure-strategy equilibria in this game, because Player 1, taking Player 2’s strategy $\mathbf{q}$ as given, can always choose $\mathbf{p}$ to maximize his own payoff, in which case Player 2 cannot be maximizing. So the game $\mathbf{G}^Q$ is quite uninteresting unless we allow mixed strategies.

A mixed strategy in $\mathbf{G}^Q$ is a probability measure on the strategy space $S_1^Q = SU_2 = S^3$, where S^3 is the three sphere. Thus the strategy spaces in $(\mathbf{G}^Q)^{\text{mixed}}$ are quite large. However, it is shown in Landsburg [8] that in equilibrium, both players can be assumed to adopt strategies supported on at most four points, and that each set of four points must lie in one of a small number of highly restrictive geometric configurations. This considerably eases the problem of searching for equilibria.

Example 4 [The Prisoner’s Dilemma]. Consider the “Prisoner’s Dilemma” game

		Player 2	
		C	D
Player 1	C	(3,3)	(0,5)
	D	(5,0)	(1,1)

There is only one Nash equilibrium, only one (classical) mixed strategy equilibrium, and only one (classical) correlated equilibrium, namely, $(\mathbf{D}, \mathbf{D})$ in every case. But it is an easy exercise to check that there are multiple mixed-strategy equilibria in the Eisert–Wilkens–Lewenstein game $\mathbf{G}^Q$.

First example: Each player chooses any of the four orthogonal quaternions and plays each of the four with equal probability. This induces the probability distribution in which each of the four payoffs is equiprobable and each player earns an expected payoff of $9/4$.

Second example: Player 1 plays the quaternions 1 and i with equal probability and Player 2 plays the quaternions j and k with equal probability. This induces the probability distribution where the payoffs $(0, 5)$ and $(5, 0)$ each occur with probability $1/2$ so that each player earns an expected payoff of $5/2$.

The techniques of Landsburg [8] reveal that, up to a suitable notion of equivalence, these are the only mixed strategy equilibria in $\mathbf{G}^Q$.

INTRODUCTION

Quasi-Newton methods are an important class of methods for solving the unconstrained optimization problem

$$\min_{x \in \mathbb{R}^n} f(x). \quad (1)$$

Newton step for Equation (1) is obtained by minimizing the second-order Taylor expansion of $f(x)$ at x_k :

$$d_k^N = -(\nabla^2 f(x_k))^{-1} g_k, \quad (2)$$

where $g_k = \nabla f(x_k)$. Newton's method has desirable properties, including fast local convergence. Let x^* be a solution of Equation (1) at which $\nabla^2 f(x^*)$ is positive definite, Newton's method converges at q-quadratically, namely,

$$\|x_k + d_k^N - x^*\| = O(\|x_k - x^*\|^2). \quad (3)$$

However, calculating $\nabla^2 f(x_k)$ is time-consuming and sometimes impossible, particularly for large-scale problems. Quasi-Newton methods are similar to Newton's method, but they do not use the second-derivative matrix $\nabla^2 f(x_k)$. Quasi-Newton methods:

$$x_{k+1} = x_k + d_k = x_k - (B_k)^{-1} g_k \quad (4)$$

can be viewed as a modification of Newton's method. B_k is an $n \times n$ matrix, which satisfies the quasi-Newton condition:

$$B_{k+1}(x_{k+1} - x_k) = g_{k+1} - g_k. \quad (5)$$

The reason for imposing Equation (5) is that we have

$$\nabla^2 f(x_{k+1})(x_{k+1} - x_k) \approx g_{k+1} - g_k. \quad (6)$$

A quasi-Newton method is also called a *variable metric method* if B_k is symmetric and positive definite, because the search direction $d_k = -B_k^{-1} g_k$ is the steepest descent direction under the metric $\|d\|_{B_k} = \sqrt{d^T B_k d}$. In a practical implementation of a quasi-Newton algorithm, either line search or trust region technique should be used to ensure global convergence. In a line search algorithm, we need to compute a steplength $\alpha_k > 0$ satisfying certain line search conditions and let

$$x_{k+1} = x_k + \alpha_k d_k = x_k - \alpha_k (B_k)^{-1} g_k. \quad (7)$$

For exact line search, we require

$$f(x_k + \alpha_k d_k) = \min_{\alpha > 0} f(x_k + \alpha d_k). \quad (8)$$

For Wolfe inexact line search, the stepsize α_k satisfies

$$f(x_k + \alpha_k d_k) < f(x_k) + c_1 \alpha_k d_k^T g_k, \quad (9)$$

$$d_k^T \nabla f(x_k + \alpha_k d_k) \geq c_2 d_k^T g_k, \quad (10)$$

where $c_2 \geq c_1$ are two constants in $(0, 1)$. In a trust region algorithm, we compute the trial step d_k by solving the trust region subproblem:

$$\min_{d \in \mathbb{R}^n} g_k^T d + \frac{1}{2} d^T B_k d \quad (11)$$

$$\text{s. t. } \|d\|_2 \leq \Delta_k, \quad (12)$$

where $\Delta_k > 0$ is the trust region bound updated from iteration to iteration.

QUASI-NEWTON UPDATES

The first quasi-Newton method was invented by Davidon [1] in 1959. Davidon's method was later reformulated by Fletcher and Powell [2];

hence it is called the Davidon, Fletcher, and Powell (DFP) method. It updates the quasi-Newton matrix by the following formula

$$B_{k+1} = B_k - \frac{B_k s_k y_k^T + y_k s_k^T B_k}{s_k^T y_k} + \left(1 + \frac{s_k^T B_k s_k}{s_k^T y_k}\right) \frac{y_k y_k^T}{s_k^T y_k}, \quad (13)$$

where $s_k = x_{k+1} - x_k$ and $y_k = g_{k+1} - g_k$. It is easy to verify that B_{k+1} defined by Equation (13) satisfies quasi-Newton condition (5). One good property of the DFP update is that B_{k+1} remains positive definite if B_k is positive definite and if $s_k^T y_k > 0$. Please notice that the condition $s_k^T y_k > 0$ is always true for a strictly convex function. Even for nonconvex functions, $s_k^T y_k > 0$ also holds if α_k satisfies either Equation (8) or (10). Let the inverse of B_k be denoted by H_k , then update formula (13) implies that

$$H_{k+1} = H_k - \frac{H_k y_k y_k^T H_k}{y_k^T H_k y_k} + \frac{s_k s_k^T}{s_k^T y_k}. \quad (14)$$

Another famous quasi-Newton update was given by Broyden [3], Fletcher [4], Goldfarb [5], and Shanno [6] independently:

$$B_{k+1} = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{y_k y_k^T}{s_k^T y_k}, \quad (15)$$

$$H_{k+1} = H_k - \frac{H_k y_k s_k^T + s_k y_k^T H_k}{y_k^T s_k} + \left(1 + \frac{y_k^T H_k y_k}{s_k^T y_k}\right) \frac{s_k s_k^T}{s_k^T y_k}. \quad (16)$$

The Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update can be obtained by interchanging H and B and interchanging s and y in the DFP update. Hence, *BFGS* is called as the *dual update of DFP*.

For any two matrices $\bar{B}$ and $\hat{B}$ satisfying the quasi-Newton condition, the line combination $\bar{B} + \theta(\hat{B} - \bar{B})$ also satisfies the quasi-Newton condition. Thus, Broyden [3] gives a

family of quasi-Newton updates:

$$B_{k+1}(\theta) = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{y_k y_k^T}{s_k^T y_k} + \theta w_k w_k^T, \quad (17)$$

where

$$w_k = \sqrt{s_k^T B_k s_k} \left(\frac{y_k}{s_k^T y_k} - \frac{B_k s_k}{s_k^T B_k s_k} \right),$$

$\theta \in \mathbb{R}^1$ being a parameter. As long as $\theta \neq 1/(1 - \beta_k \gamma_k)$, where $\beta_k = y_k^T H_k y_k / s_k^T y_k$ and $\gamma_k = s_k^T B_k s_k / s_k^T y_k$, we have

$$H_{k+1}(\phi) = H_k - \frac{H_k y_k y_k^T H_k}{y_k^T H_k y_k} + \frac{s_k s_k^T}{s_k^T y_k} + \phi v_k v_k^T, \quad (18)$$

where

$$v_k = \sqrt{y_k^T H_k y_k} \left(\frac{s_k}{s_k^T y_k} - \frac{H_k y_k}{y_k^T H_k y_k} \right),$$

and $\phi = \phi(\theta) = (1 - \theta)/(1 + \theta(\beta_k \gamma_k - 1))$. If $\theta > 1/(1 - \beta_k \gamma_k)$, we call the updates defined by Equation (17) as a Broyden-positive family because $B_{k+1}(\theta)$ is positive definite as long as B_k is positive definite and $s_k^T y_k > 0$. If we restrict $\theta \in [0, 1]$, updates defined by Equation (17) are called a *Broyden convex family*.

Different values of the parameter θ lead to different quasi-Newton updates. If we let $\theta = 1/(1 - \gamma_k)$, formula (17) becomes the symmetric rank-1 (SR1) update

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k)(y_k - B_k s_k)^T}{(y_k - B_k s_k)^T s_k}, \quad (19)$$

$$H_{k+1} = H_k + \frac{(s_k - H_k y_k)(s_k - H_k y_k)^T}{(s_k - H_k y_k)^T y_k}, \quad (20)$$

which is given by Broyden [7], Davidon [8], Fiacco and McCormick [9], and Murtagh and Sargent [10] independently. It is easy to see that the dual update of SR1 is still SR1. Therefore, we call SR1 a *self-dual update*. By choosing $\theta = 1/(1 + \gamma_k)$, $1/(1 + \sqrt{\beta_k \gamma_k})$ and

$(\beta_k - 1)/(\beta_k \gamma_k - 1)$ respectively, we obtain the Hoshino [11] update

$$B_{k+1} = B_k - \frac{(B_k s_k + y_k)(B_k s_k + y_k)^T}{s_k^T y_k + s_k^T B_k s_k} + 2 \frac{y_k y_k^T}{s_k^T y_k}, \quad (21)$$

the Xie [12] update

$$B_{k+1} = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{y_k y_k^T}{s_k^T y_k} + \frac{1}{1 + \sqrt{\beta_k \gamma_k}} w_k w_k^T, \quad (22)$$

and the Yuan [13] update

$$B_{k+1} = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{y_k y_k^T}{s_k^T y_k} + \frac{\beta_k - 1}{\beta_k \gamma_k - 1} w_k w_k^T. \quad (23)$$

It is easy to see that all the update formulae in Equations (21)–(23) are self-dual updates.

A family of update formulae with three parameters were given by Huang [14]:

$$H_{k+1} = H_k - \frac{H_k y_k y_k^T H_k}{y_k^T H_k y_k} + \rho_k \frac{s_k s_k^T}{s_k^T y_k} + (\tau_k s_k + \xi_k H_k y_k) v_k^T, \quad (24)$$

where ρ_k , τ_k , ξ_k are three parameters, and v_k is defined above. The inverse form of the above update formula is

$$B_{k+1} = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{1}{\rho_k} \frac{y_k y_k^T}{s_k^T y_k} + (\tau'_k y_k + \xi'_k B_k s_k) w_k^T. \quad (25)$$

If we require B_{k+1} symmetric, we obtain the Huang symmetric family

$$H_{k+1} = H_k - \frac{H_k y_k y_k^T H_k}{y_k^T H_k y_k} + \rho_k \frac{s_k s_k^T}{s_k^T y_k} + \phi_k v_k v_k^T. \quad (26)$$

A special update of the Huang family is

$$B_{k+1} = B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \frac{1}{\rho_k} \frac{y_k y_k^T}{s_k^T y_k}, \quad (27)$$

which can be viewed as a modified BFGS method. Specific choices of the value $1/\rho_k$ include $[2(f(x_k) - f(x_{k+1}) + s_k^T g_{k+1})/s_k^T y_k]$ [15] and $[s_k^T(4g_{k+1} + 2g_k) + 6(f(x_k) - f(x_{k+1}))]/s_k^T y_k]$ [16,17].

It is easy to see that Broyden family can be obtained from Huang family by requiring the quasi-Newton condition (5) and symmetric condition

$$B_{k+1} = B_{k+1}^T. \quad (28)$$

The update formulae discussed so far are all rank-2 updates, in the sense that the rank of the increment matrix $B_{k+1} - B_k$ is at most two.

It is easy to show that any rank-1 quasi-Newton update must be in the following form:

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k) c_k^T}{c_k^T s_k}, \quad (29)$$

where c_k satisfies $c_k^T s_k \neq 0$. A similar form for the inverse update was first given by McCormick (see Ref. 18). If we let $c_k = s_k$, $B_k^T s_k$, and y_k respectively in the above formula, we obtain Broyden unsymmetric Rank-1 [19] update

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k) s_k^T}{s_k^T s_k}, \quad (30)$$

the McCormick update [20]

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k) s_k^T B_k}{s_k^T B_k s_k}, \quad (31)$$

and the Pearson update [18]

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k) y_k^T}{s_k^T y_k}. \quad (32)$$

It is easy to see that the Pearson update is the dual update of the McCormick update. If $u_k = B_k^T y_k$, Equation (29) is

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k) y_k^T B_k}{y_k^T B_k s_k}, \quad (33)$$

which is obtained by Broyden [19], and is called *Broyden's other method* or *Broyden's poor method* [21].

An important rank-2 update that does not belong to Broyden family is the symmetrization of Broyden's unsymmetric update (30):

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k) s_k^T + s_k (y_k - B_k s_k)^T}{s_k^T s_k} - \frac{s_k^T (y_k - B_k s_k) s_k s_k^T}{(s_k^T s_k)^2}, \quad (34)$$

which was first obtained by Powell [22], and is called *Powell's symmetric Broyden* (PSB) update. Powell's technique can be used to symmetrize the general rank-1 update (29) to obtain the Dennis–Moré [21,23] update

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k) c_k^T + c_k (y_k - B_k s_k)^T}{c_k^T s_k} - \frac{s_k^T (y_k - B_k s_k) c_k c_k^T}{(c_k^T s_k)^2}. \quad (35)$$

It is easy to see that DFP is a special case of Equation (35) when $c_k = y_k$. Moreover, if $c_k = y_k + t w_k$, (35) is Broyden family (17) with $\theta = (1 + t \sqrt{s_k^T B_k s_k / s_k^T y_k})^2 - t^2 / s_k^T y_k$. Hence all updates in Broden convex family ($\theta \in [0, 1]$) are special cases of Equation (35), for example, BFGS is a special case of Equation (35) when $c_k = y_k \sqrt{s_k^T y_k} + B_k s_k \sqrt{s_k^T B_k s_k}$. Moreover the SR1 is also a special case of Equation (35) when $c_k = y_k - B_k s_k$.

Davidon [24] generalized the Broyden family to the following family

$$H_{k+1} = H_k - \frac{H_k \bar{y}_k \bar{y}_k^T H_k}{\bar{y}_k^T H_k \bar{y}_k} + \frac{\bar{s}_k \bar{s}_k^T}{\bar{s}_k^T \bar{y}_k} + \phi \bar{v}_k \bar{v}_k^T, \quad (36)$$

where ϕ is a parameter and $\bar{v}_k = \sqrt{\bar{y}_k^T H_k \bar{y}_k}$ $\left(\frac{\bar{s}_k}{\bar{s}_k^T \bar{y}_k} - \frac{H_k \bar{y}_k}{\bar{y}_k^T H_k \bar{y}_k} \right)$ with $\bar{s}_k$ and $\bar{y}_k \in \mathbb{R}^n$ satisfying $\bar{s}_k - H_k \bar{y}_k = s_k - H_k y_k$ and $\bar{y}_k^T \bar{s}_k = \bar{y}_k^T s_k = y_k^T \bar{s}_k$. When $\bar{s}_k = s_k$ and $\bar{y}_k = y_k$, Davidon reduces to the Broyden family.

Another class of update formulae has the following form:

$$B_{k+1} = \rho \left(B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} + \theta w_k w_k^T \right) + \frac{y_k y_k^T}{s_k^T y_k}. \quad (37)$$

They are called *self-scaling update formulae*, which was first given by Oren [25]. One such specific formula is the self-scaling BFGS update [26,27]:

$$B_{k+1} = \frac{s_k^T y_k}{s_k^T B_k s_k} \left(B_k - \frac{B_k s_k s_k^T B_k}{s_k^T B_k s_k} \right) + \frac{y_k y_k^T}{s_k^T y_k}. \quad (38)$$

As given above, there are lots of different quasi-Newton updates. It is natural to question which quasi-Newton update is the best one. Numerical results indicate that the BFGS method is one of the most efficient quasi-Newton methods. Powell [28] studied the global behavior of BFGS and DFP by considering special quadratic objective functions. However, there are no firm theoretical results showing that the BFGS is better than other quasi-Newton methods. Though efforts for searching for better quasi-Newton updates have never been stopped, it seems very unlikely to find a quasi-Newton method that is much better the BFGS method.

INVARIANCE AND QUADRATIC TERMINATION

One important property of quasi-Newton method is invariance, namely, that it is not affected by linear transformations. Let A be a nonsingular matrix, $a \in \mathbb{R}^n$; consider the linear transformation

$$\tilde{x} = Ax + a, \quad (39)$$

the objective function is now

$$\tilde{f}(\tilde{x}) = f(A^{-1}(\tilde{x} - a)) = f(x). \quad (40)$$

It is easy to see that

$$\nabla_{\tilde{x}} \tilde{f}(\tilde{x}) = A^{-T} \nabla f(x). \quad (41)$$

The following result is obvious (for example, see Ref. 29).

Lemma 1. *Assume that $\tilde{x}_k = Ax_k + a$, and $\tilde{H}_k = AH_kA^T$, then $\tilde{d}_k = -\tilde{H}_k\tilde{g}_k = Ad_k$ and $\tilde{d}_k^T\tilde{g}_k = d_k^Tg_k$. Furthermore, if $\tilde{\alpha}_k = \alpha_k$, we have $\tilde{x}_{k+1} = Ax_{k+1} + a$, and $\tilde{y}_k = A^{-T}y_k$.*

The above lemma indicates that a quasi-Newton method is invariant as long as $\tilde{\alpha}_k = \alpha_k$ and $\tilde{H}_k = AH_kA^T$ holds for all k . It is obvious that $\tilde{\alpha}_k = \alpha_k$ if exact line searches are used. If inexact line search conditions are based on $f(x_k)$, $d_k^T\nabla f(x_k)$, $f(x_k + \alpha d_k)$, $d_k^T\nabla f(x_k + \alpha d_k)$, we can see that the same value of $\tilde{\alpha}_k$ and α_k will be accepted. Assume $\tilde{\alpha}_k = \alpha_k$; because $s_k^Ty_k$, $s_k^TB_k s_k$ and $y_k^TH_k y_k$ are all invariant scalars, we can easily show that $\tilde{H}_{k+1} = A\tilde{H}_{k+1}A^T$ if $\tilde{H}_{k+1}$ and H_{k+1} are generated by the same update formula in the Huang family. Thus, by induction we can establish the following theorem.

Theorem 1. *Any method in Huang family is invariant if α_k is determined by tests on $f(x_k)$, $d_k^T\nabla f(x_k)$, or other invariant scalars.*

It is due to this invariance property that we can always assume $H_1 = I$ for studying any quasi-Newton method. The following result is obtained under this assumption.

Theorem 2. *Assume that*

$$f(x) = g^Tx + \frac{1}{2}x^TGx, \quad (42)$$

where $g \in \mathbb{R}^n$ and G is a symmetric positive definite matrix. Let $H_1 = I$; α_k is obtained by exact line searches and $H_k (k > 1)$ are generated by an update formula from the Huang symmetric family (26). Then, for all k we have

$$\begin{aligned} s_i^T\nabla f(x_{k+1}) &= 0, & i &= 1, \dots, k, \\ H_{k+1}y_i &= \rho_i s_i, & i &= 1, \dots, k, \\ s_k^T G s_j &= 0, & i &\neq j; i, j = 1, \dots, k+1. \end{aligned}$$

The above theorem shows that the steps s_i ($i = 1, \dots, k$) are mutual G-conjugate. Thus,

we have the following the quadratic termination result.

Theorem 3. *Under the assumptions of Theorem 2, if $g_k^TH_k g_k \neq 0$ as long as $g_k \neq 0$, there exists $m \leq n$ such that $\|g_{m+1}\| = 0$ and the iterates $\{x_k\}$ are the same as generated by the conjugate gradient method.*

A direct corollary of the above theorem is that all methods in Broyden-positive family has quadratic termination. Quadratic termination was first noticed by Myers [30] for the DPF method.

Because the invariance property of quasi-Newton methods, Theorem 2 is also true if we replace the condition $H_1 = I$ by H_1 being any symmetric positive definite matrix.

From the proof of Theorem 2 (for example, see Ref. 29), the quadratic termination of quasi-Newton methods depends on exact line searches. However, for the SR1 method, this condition is not needed.

Theorem 4. *Assume that H_1 is any symmetric matrix, and that H_{k+1} is given by SR1 update (20). If for $k = 1, 2, \dots, n$, $(s_k - H_k y_k)^Ty_k \neq 0$, and if $s_1, s_2, \dots, s_n$ are linearly independent, we have that $H_{n+1} = H^{-1}$.*

LEAST CHANGE AND ERROR BOUND

The main idea of quasi-Newton methods is to update the quasi-Newton matrix B_k so that (hopefully) it approaches to the Hessian of the objective function $\nabla^2 f(x)$. Because each quasi-Newton matrix B_k satisfies the quasi-Newton condition in the previous search direction, it is reasonable to require B_{k+1} to be not too far away from B_k . Actually many quasi-Newton updates do have certain least-change properties, namely, B_{k+1} minimizes certain norms of $B_{k+1} - B_k$, subject to the quasi-Newton condition (5).

Following the notation of Dennis Jr. and Schnabel [31], define the set

$$Q(y, s) = \{B \in \mathbb{R}^{n \times n} | Bs = y\}. \quad (43)$$

Theorem 5. *Broyden unsymmetric update (30) is the solution of the problem*

$$\min \|B - B_k\|_2, \quad (44)$$

$$\text{s. t. } B \in Q(y_k, s_k). \quad (45)$$

For any $n \times n$ nonsingular symmetric matrix M , we define the matrix norm $\|\cdot\|_{M,F}$ by $\|A\|_{M,F} = \|MAM\|_F$. We have the following theorem [23]:

Theorem 6. *Let $B \in \mathbb{R}^{n \times n}$ symmetric, $s, y \in \mathbb{R}^n$, $M \in \mathbb{R}^{n \times n}$ symmetric and nonsingular. The unique solution for problem*

$$\min \|A - B\|_{M,F} \quad (46)$$

$$\text{s. t. } A \in Q(y, s), \quad A = A^T \quad (47)$$

is

$$B_+ = B + \frac{(y - Bs)s^T M^{-2} + M^{-2}s(y - Bs)^T}{s^T M^{-2}s} - \frac{(y - Bs)^T s}{(s^T M^{-2}s)^2} M^{-2} s s^T M^{-2}. \quad (48)$$

Please notice that, if we let $c = M^{-2}s$, the above general least change update (48) is Dennis–Moré update (35), which is essentially the Broyden family (17).

From the above theorem, we can get the following results.

Corollary 1. *Assume that B_k is symmetric, B_{k+1} defined by PSB update (34) is the solution of*

$$\min \|B - B_k\|_F, \quad (49)$$

$$\text{s. t. } B \in Q(y_k, s_k), \quad B = B^T. \quad (50)$$

Corollary 2. *Assume that B_k is symmetric, $s_k^T y_k > 0$. Let M be any symmetric nonsingular matrix M that satisfies $M^{-2}s_k = y_k$, the solution of problem*

$$\min \|B - B_k\|_{M,F} \quad (51)$$

$$\text{s. t. } B \in Q(y_k, s_k), \quad B = B^T \quad (52)$$

is the DFP update (13).

Corollary 3. *Assume that H_k is symmetric, $s_k^T y_k > 0$. Let M be any symmetric nonsingular matrix M that satisfies $M^{-2}s_k = y_k$, the solution of problem*

$$\min \|H - H_k\|_{M^{-1},F} \quad (53)$$

$$\text{s. t. } H \in Q(s_k, y_k), \quad H = H^T \quad (54)$$

is the BFGS update (16).

Another least change from B_k to B_{k+1} is to require that $B_k^{-1/2} B_{k+1} B_k^{-1/2}$ is as close as possible to the identity matrix I . Byrd and Nocedal [32] suggest the matrix function

$$\psi(A) = \text{tr}(A) - \ln(\det(A)), \quad (55)$$

which is well defined for all symmetric positive definite matrices and which achieves its minimum at $A = I$. Fletcher [33] established the following result.

Theorem 7. *Assume that B_k is symmetric and positive definite, and $s_k^T y_k > 0$. Then, problem*

$$\min \psi(B_k^{-1/2} B B_k^{-1/2}) \quad (56)$$

$$\text{s. t. } B \in Q(y_k, s_k), \quad B = B^T \quad (57)$$

is the matrix B_{k+1} defined by BFGS update (15).

In addition to least change property, quasi-Newton updates have another desirable property that the new quasi-Newton matrix is closer to the Hessian of the objective function than the previous one in certain sense. First, let us consider the special case when the objective function is strictly convex and quadratic. When we need to show B_{k+1} is closer to the Hessian matrix G of the objective function than B_k . Fletcher [4] discovered that Broyden convex family has the following desirable property.

Theorem 8. *Let $f(x)$ be given by Equation (42), H_1 symmetric and positive definite,*

$H_k (k > 1)$ be generated by Broyden convex family. Assume that $\sigma_i^{(k)} = \sigma_i(G^{\frac{1}{2}} H_k G^{\frac{1}{2}})$ is the i th largest eigenvalue of $G^{\frac{1}{2}} H_k G^{\frac{1}{2}}$, then

$$\min \left\{ \sigma_i^{(k)}, 1 \right\} \leq \sigma_i^{(k+1)} \leq \max \left\{ \sigma_i^{(k)}, 1 \right\}. \quad (58)$$

All updates in Broyden convex family can be expressed in the form of the general least change update (48), which has the following desirable error bound property.

Theorem 9. Let B_+ be given by update formula (48), and let G be any symmetric matrix satisfying $y = Gs$, then

$$\begin{aligned} \|B_+ - G\|_{M,F}^2 &\leq \|B - G\|_{M,F}^2 - \frac{\|M(B - G)s\|_2^2}{\|M^{-1}s\|_2^2} \\ &= \|B - G\|_{M,F}^2 - \frac{\|M(Bs - y)\|_2^2}{\|M^{-1}s\|_2^2}. \end{aligned} \quad (59)$$

The above theorem indicates that B_+ , comparing to B_k , is closer to G . Inequality (59) is very useful in the study of convergence of quasi-Newton methods.

CONVERGENCE RESULTS

The convergence analysis for quasi-Newton methods have been studied in the past few decades. There are already plenty results on this interesting topic. However, there are still open problems remaining to be solved, for example, the global convergence of the DFP method.

First we consider the case where exact line searches are used.

For general convex functions, Powell [34] established the convergence of DFP method.

Theorem 10. Assume that $f(x)$ is uniformly convex and twice continuously differentiable. Then, $\{x_k\}$ generated by the DFP method with exact line search converges to the unique minimizer x^* of $f(x)$. Moreover, the convergence rate is Q -superlinear, namely,

$$\lim_{k \rightarrow \infty} \frac{\|x_{k+1} - x^*\|}{\|x_k - x^*\|} = 0. \quad (60)$$

Dixon [35,36] proved that all methods in Huang family generate the identical sequence $\{x_k\}$ if exact line searches are used. Therefore, Theorem 10 and Dixon's results ensure that exact line search ensures that all quasi-Newton methods in the Huang family will converge superlinearly for uniformly convex functions. For nonconvex objective functions, if $n = 2$, Powell [37] proved that the DFP method ensures the weak convergence result:

$$\liminf_{k \rightarrow \infty} \|g_k\| = 0, \quad (61)$$

if a special exact line search is used, namely, if α_k is the largest number that $f(x_k + \alpha d_k)$ decreases monotonically for $0 \leq \alpha \leq \alpha_k$. If the sequence $\{x_k\}$ generated by the DFP method with exact line searches converges to a point, it can be shown [38] that

$$\lim_{k \rightarrow \infty} \|g_k\|_2 = 0. \quad (62)$$

It is shown by Burmeister [39] and by Schuller and Stoer [40] that the DFP and Broyden family converge to an n -step quadratic, namely, there exists a constant c such that

$$\|x_{k+n} - x^*\|_2 \leq c \|x_k - x^*\|_2^2 \quad (63)$$

holds for all k .

Ritter [41] improves Equation (63) to

$$\|x_{k+n} - x^*\|_2 = o\left(\|x_k - x^*\|_2^2\right). \quad (64)$$

Suppose we define the matrix U_k by

$$U_k = [d_{k+1}/\|d_{k+1}\|_2, \dots, d_{k+n}/\|d_{k+n}\|_2]. \quad (65)$$

Schuller [42] proved that

$$\|x_{k+n} - x^*\| = O\left(\|x_{k+n-1} - x^*\| \|x_{k-1} - x^*\|\right). \quad (66)$$

under the assumption that

$$\limsup_{k \rightarrow \infty} \|U_k^{-1}\|_2 < +\infty \quad (67)$$

The above bound was improved to

$$\|x_{k+n} - x^*\| = O(\|x_{k+n-1} - x^*\| \|x_k - x^*\|). \quad (68)$$

if Equation (67) holds [41]. However, Equation (67) is a very strong condition as it is easy to construct examples that all U_k are singular matrices.

Without assuming Equation (67), the best local Q-suplinearly convergence result is given by Powell [43]:

$$\|x_{k+n} - x^*\| = O(\|x_{k+1} - x^*\| \|x_k - x^*\|). \quad (69)$$

When $n = 2$, Equations (69) and (68) are the same, which is the optimal convergence rate. When $n > 2$, Equation (69) is weaker than Equation (68). Numerical tests indicate that Equation (68) is always true. Moreover, if U_k is singular, and the iterate points are all in a lower dimension subspace, we would have a faster convergence rate. But, to prove Equation (68) without assuming Equation (67) is still an open problem.

From Ortega and Rheinboldt [44], Newton's method with exact line searches converges Q-quadratically. By giving a three-time continuously differentiable example, Powell [43] shows that the Q-order of the quasi-Newton method can be less than 2. It is shown by Yuan [45] that the least Q-order of quasi-Newton method is only 1, for all twice continuously differentiable functions.

Now we consider a special case that $\alpha_k \equiv 1$. This special case is of interest. First, most line search techniques try the unit steplength first. Secondly, when x_k converges to a solution, most quasi-Newton methods (such as DFP, BFGS) with unit steplength satisfy the inexact line search conditions.

Many important results are given by Dennis and Moré [23]. One of them is given as follows.

Theorem 11. *Assume that $f(x)$ is twice continuously differentiable and $\nabla^2 f(x)$ is Lipschitz continuous. Let x^* be a minimizer of $f(x)$ and $\nabla^2 f(x^*)$ positive definite. Then the DFP method and the BFGS method with $\alpha_k = 1$*

converges locally Q-superlinearly if x_1 is sufficiently close to x^ and B_1 is sufficiently close to $\nabla^2 f(x^*)$.*

The key technique for proving the above theorem and other local convergence results is by first showing Q-linear convergence [23]. The local Q-linear convergence is proved by using the following error bound [46]

$$\|B_{k+1} - \nabla^2 f(x^*)\|_{M,F} \leq (1 + \eta_1 \sigma(x_k, x_{k+1})) \|B_k - \nabla^2 f(x^*)\|_{M,F} + \eta_2 \sigma(x_k, x_{k+1}), \quad (70)$$

for some fixed matrix M and positive constants η_1, η_2 , where $\sigma(x, \bar{x}) = \max[\|x - x^*\|, \|\bar{x} - x^*\|]$. Once the local Q-linear convergence is proved, inequality (59) implies that

$$\lim_{k \rightarrow \infty} \frac{\|(B_k - \nabla^2 f(x^*))s_k\|}{\|s_k\|} = 0. \quad (71)$$

The above relation ensures that $\|x_k + d_k - x^*\|/\|x_k - x^*\| \rightarrow 0$, which shows that $\alpha_k = 1$ implies Q-superlinearly convergence [47]. It is easy to see that the above theorem is also true if we replace $\alpha_k = 1$ by $\alpha_k \rightarrow 1$. Limit (71) also implies that $\alpha_k^* \rightarrow 1$, where α_k^* is the stepsize obtained by exact line search. Thus, it can be shown that $\alpha_k = 1$ is acceptable for all sufficiently large k if Wolfe inexact line search is used. Therefore, we know that both BFGS and DFP methods with the special Wolfe inexact line search (always trying $\alpha_k = 1$ first) are locally superlinearly convergent. For local convergence results of other quasi-Newton methods, please see Refs 23, 48.

Now, we consider global convergence of quasi-Newton methods with inexact line searches. The following pioneering result was obtained by Powell [49].

Theorem 12. *Assume that $f(x)$ is convex, and twice continuously differentiable in $\{x; f(x) \leq f(x_1)\}$. For any positive definite B_1 , the BFGS method with Wolfe line search x_k either terminates finitely or Equation (62) holds.*

The above result is extended from BFGS method to all methods in the Broyden convex family except DFP [50].

Theorem 13. *Under the assumptions of the above theorem, let B_{k+1} be given by Broyden convex family, namely, $B_{k+1} = B_{k+1}(\theta_k)$, if there exists $\delta > 0$, such that $1 - \theta_k \geq \delta$, then either $\{x_k\}$ terminates finitely or Equation (62) holds.*

The proof of the above theorem cannot be extended to the DFP method, which lacks the “self-correction” $-B_k s_k s_k^T B_k / s_k^T B_k s_k$. Therefore, the convergence of the DFP method with inexact line search remains as an open problem [51]:

Open Question 1. *Assume that the objective function $f(x)$ is uniformly convex and twice continuously differentiable. Does the DFP method with Wolfe inexact line search converge to the unique minimizer of $f(x)$ for any starting point x_1 and any positive definite initial matrix B_1 ?*

It would be interesting and important to solve the above open question, as the DFP method is the very first quasi-Newton method invented. However, up to now, we are not able to prove the convergence nor able to construct counterexamples. Under additional assumptions, we can give a positive answer to the above open question [52].

Theorem 14. *If either $\|g_k\|_2$ is monotone or $\sum_{k=1}^{\infty} \|s_k\|_2 < \infty$, DFP method with inexact line searches guarantees Equation (62).*

For nonconvex functions, there are no global convergence results for quasi-Newton methods with Wolfe inexact line search. Nocedal [51] gives another open question.

Open Question 2. *Assume that the objective function is twice continuously differentiable and bounded below. Does the BFGS method with Wolfe inexact line search ensure Equation (61) for any starting point x_1 and any positive definite initial matrix B_1 ?*

It is known [53] that Equation (61) may fail for the PRP (Polyak, Polak, and Ribière) method and the BFGS method if α_k is allowed to be any local minimizer of $f(x_k + \alpha d_k)$. A counterexample given in Powell [53] that the BFGS method cycles nearly 8 points. Owing

to Dixon [36], Powell’s counterexample is also valid for other methods in the Broyden family. Moreover, Dai [54] observed that Powell’s counterexample satisfies the Wolfe inexact line search condition if $c_1 < 1/84$. Hence, we have the negative answer for Open Question 2.

Theorem 15. *Consider the BFGS method with Wolfe line search. If $c_1 \leq 1/84$, then for any $n > 2$ there exists a starting point x_1 and a C^∞ function $f(x)$ in $\mathbb{R}^n$ such that Equation (61) fails.*

Dai [54] also gives a two-dimensional example that the BFGS method with Wolfe line search cycles nearly 6 points and Equation (61) does not hold.

LIMITED MEMORY AND SUBSPACE TECHNIQUE

For medium- and small-scale problems, quasi-Newton methods are very efficient, and the BFGS method is one of most widely used algorithm for solving medium- and small-scale problems. However, for large-scale problems (when n is very very large), a quasi-Newton method needs huge storage and the linear algebra computation cost per iteration is very high.

Limited memory quasi-Newton methods try to reduce the memory requirement, while maintain certain quasi-Newton property. Limited memory quasi-Newton methods were first proposed as an extension of the conjugate gradient methods by Perry [55] and Shanno [56], and studied by many others, including Gill and Murray [57], Buckley [58], Buckley and LeNir [59], and Nocedal [60].

Let us write the BFGS update (16) in the following form

$$H_{k+1} = \left(I - \frac{s_k y_k^T}{s_k^T y_k} \right) H_k \left(I - \frac{y_k s_k^T}{s_k^T y_k} \right) + \frac{s_k s_k^T}{s_k^T y_k}. \quad (72)$$

Let $\rho_k = 1/s_k^T y_k$ and $V_k = (I - \rho_k y_k s_k^T)$; applying Equation (72), repeatedly, gives the following formula

$$\begin{aligned} H_{k+1} &= (V_k^T \cdots V_{k-i}^T) H_{k-i} (V_{k-i} \cdots V_k) \\ &\quad + \sum_{j=0}^i \rho_{k-i+j} \left(\prod_{l=0}^{i-j-1} V_{k-l}^T \right) s_{k-i+j} s_{k-i+j}^T \\ &\quad \times \left(\prod_{l=0}^{i-j-1} V_{k-l} \right)^T. \end{aligned} \quad (73)$$

Thus, the $m+1$ step limited memory BFGS method uses the following update

$$\begin{aligned} H_{k+1} &= V_k^T \cdots V_{k-m}^T H_k^{(0)} V_{k-m} \cdots V_k \\ &\quad + \sum_{j=0}^m \rho_{k-m+j} \left(\prod_{l=0}^{m-j-1} V_{k-l}^T \right) s_{k-m+j} s_{k-m+j}^T \\ &\quad \times \left(\prod_{l=0}^{m-j-1} V_{k-l} \right)^T, \end{aligned} \quad (74)$$

where $H_k^{(0)}$ can be a simple scale matrix σI . Assume we know $H_k^{(0)}$, we only need to store $s_i, y_i (i = k-m, \dots, k)$. One particular $H_k^{(0)}$ is $H_k^{(0)} = \frac{s_k^T y_k}{\|y_k\|_2^2} I$. Other choices of $H^{(0)}$ can be found in Liu and Nocedal [61].

Another approach for reducing storage and computing cost is the subspace technique. Subspace quasi-Newton methods are based on the following result (for example, see Ref. 62).

Theorem 16. *Consider the BFGS method applied to a general nonlinear function. If $H_1 = \sigma I (\sigma > 0)$, then the search direction $d_k \in \mathcal{G}_k = \text{SPAN}\{g_1, g_2, \dots, g_k\}$ for all k . Moreover, if $z \in \mathcal{G}_k$ and $w \in \mathcal{G}_k^\perp$, then $H_k z = \mathcal{G}_k$ and $H_k w = \sigma w$.*

Actually, it is easy to see that the above theorem is also true if the BFGS method is replaced by any method in the Broyden family. Owing to this subspace property, in iteration k , we can obtain the search direction d_k by solving a subproblem defined in the lower dimensional subspace $\mathcal{G}_k$ instead of working

in the whole space $\mathfrak{R}_n$. Let $r_k = \dim(\mathcal{G}_k)$ and $z_1, z_2, \dots, z_{r_k}$ be an orthonormal base of $\mathcal{G}_k$. Let $Z_k = [z_1, z_2, \dots, z_{r_k}]$ and define $\bar{g}_k = Z_k^T g_k$ and $\bar{B}_k = Z_k^T B_k Z_k$. Then, the search direction is

$$d_k = -Z_k (\bar{B}_k)^{-1} \bar{g}_k. \quad (75)$$

Owing to Theorem 16, if B_{k+1} is updated by the BFGS formula, $\bar{B}_{k+1}$ can be obtained by the BFGS update formula in the subspace directly. If $r_{k+1} = r_k$, we have

$$\bar{B}_{k+1} = \bar{B}_k - \frac{\bar{B}_k \bar{s}_k \bar{s}_k^T \bar{B}_k}{\bar{s}_k^T \bar{B}_k \bar{s}_k} + \frac{\bar{y}_k \bar{y}_k^T}{\bar{s}_k^T \bar{y}_k}, \quad (76)$$

where $\bar{s}_k = Z_k^T s_k$ and $\bar{y}_k = Z_k^T y_k$. If $r_{k+1} = r_k + 1$, we have

$$\bar{B}_{k+1} = \hat{B}_k - \frac{\hat{B}_k \bar{s}_k \bar{s}_k^T \hat{B}_k}{\bar{s}_k^T \hat{B}_k \bar{s}_k} + \frac{\bar{y}_k \bar{y}_k^T}{\bar{s}_k^T \bar{y}_k} \quad (77)$$

where

$$\hat{B}_k = \begin{pmatrix} \bar{B}_k & 0 \\ 0 & \sigma \end{pmatrix}$$

and

$$\bar{s}_k = Z_{k+1} s_k, \quad \bar{y}_k = Z_{k+1}^T g_{k+1} - \begin{pmatrix} Z_k^T g_k \\ 0 \end{pmatrix}.$$

Thus, we can have a subspace BFGS method, which defines the search direction by Equation (75) with $\bar{B}_1 = \sigma$, and $\bar{B}_k (k \geq 2)$ being updated by Equations (76) and (77). It is proved [62] that the subspace BFGS method and conventional BFGS method in the full space generate the identical iterate sequence $\{x_k\}$. A similar result is also true for quasi-Newton methods with trust regions [63].

Another type of special quasi-Newton methods is that the quasi-Newton matrices are sparse. Schubert [64] is the first to study sparse quasi-Newton updates where a sparse unsymmetric rank-1 update is proposed for solving nonlinear equations. For unconstrained optimization, earliest work on sparse quasi-Newton method was given by Powell and Toint [65] and Toint [66].

For example, if we know that the Hessian of the objective has sparse structure:

$$\left(\nabla^2 f(x)\right)_{ij} = 0, \quad \text{for } (i, j) \in \mathcal{I}, \quad (78)$$

where $\mathcal{I}$ is a set of ordered pairs of integers in the range 1 to n , it is reasonable to require $(B_k)_{ij} = 0$ for $(i, j) \in \mathcal{I}$ and all k . Given B_k satisfying $(B_k)_{ij} = 0$ for $(i, j) \in \mathcal{I}$, Toint [66] suggests to define B_{k+1} by

$$\min \|B - B_k\|_{M, F} \quad (79)$$

$$\text{s. t. } B \in \mathcal{Q}(y_k, s_k), \quad B = B^T \quad (80)$$

$$(B)_{ij} = 0, \quad \text{for } (i, j) \in \mathcal{I}. \quad (81)$$

The solution for problems (79)–(81) can be obtained by solving its corresponding KKT (Karush, Kuhn, and Tucker) system, for details please see Refs 66, 67.

It is quite often that large-scale problems have separable structure, namely, the objective functions are in the following form:

$$f(x) = \sum_{i=1}^m f_i(x), \quad (82)$$

where each of the functions $f_i(x)$ depends only on a few variables. Thus, the partitioned quasi-Newton method defines the search direction by

$$d_k = -\left(\sum_{i=1}^m B_k^{(i)}\right)^{-1} g_k, \quad (83)$$

where each $B_k^{(i)}$ ($i = 1, \dots, m$) satisfies the corresponding quasi-Newton condition

$$B_k^{(i)}(x_k - x_{k-1}) = \nabla f_i(x_k) - \nabla f_i(x_{k-1}). \quad (84)$$

For more details about the partitioned quasi-Newton methods, please see Refs 68–72.

PRACTICAL IMPLEMENTATIONS

In an iteration of a line search quasi-Newton algorithm, the main computation cost is the calculation of the search direction

$d_k = -B_k^{-1}g_k$. If we generate B_k by a quasi-Newton update, the line system

$$B_k d = -g_k \quad (85)$$

needs to be solved. Solving a system of n linear equations requires $O(n^3)$ operations. If we generate H_k directly, $d_k = -H_k g_k$ can be obtained by $O(n^2)$ operations. However, updating H_k is not as stable as updating B_k . One simple explanation is that updating B_k needs $y_k y_k^T / s_k^T y_k$, while updating H_k requires $s_k s_k^T / s_k^T y_k$. Assuming the errors for computing s_k and y_k are both in the magnitude of ε , then the error bounds for computing $y_k y_k^T / s_k^T y_k$ and $s_k s_k^T / s_k^T y_k$ are $O(\varepsilon \|y_k\|_2^2 / s_k^T y_k)$ and $O(\varepsilon \|s_k\|_2^2 / s_k^T y_k)$ respectively. It is easy to see for functions that $\nabla^2 f(x)$ satisfy Lipschitz condition, there exists constant M such that $\|y_k\|_2^2 < M s_k^T y_k$. But on the other hand, it is possible that $\|s_k\|_2^2 / s_k^T y_k \rightarrow \infty$.

In order to update B_k directly while avoiding solving equation (85), Gill and Murray [73] suggest to decompose B_k by LDL^T , where L is a unit lower triangle and D is a diagonal matrix. Then we update both L and D . Because any rank-2 update formulae can be written as

$$B_{k+1} = B_k + \tau_k u_k u_k^T + \xi_k z_k z_k^T, \quad (86)$$

where $\tau_k, \xi_k \in \mathbb{R}$, $u_k, z_k \in \mathbb{R}^n$. Therefore we only need to consider the LDL^T factorization of

$$LDL^T + \tau z z^T. \quad (87)$$

It is easy to see that the above relation can be written as

$$L(D + \tau \bar{z} \bar{z}^T)L^T, \quad (88)$$

where $\bar{z}$ is obtained by solving $L\bar{z} = z$. Hence, the problem now is how to obtain the LDL^T factorization of the sum of a diagonal matrix and a rank-1 matrix. The computation cost for the LDL^T factorization of Equation (87) is about $\frac{3}{2}n^2$ operations. Thus, if we have $B_k = L_k D_k L_k^T$, obtaining the LDL^T of B_{k+1} given by Equation (86) needs about $3n^2$ operations. Once we have

the LDL^T factorization, the search direction d_k can be easily obtained by solving $L_k D_k L_k^T d = -g_k$, which requires solving two triangle linear systems. Thus, the operations for updating the quasi-Newton matrix and computing the search direction for each iteration are in the magnitude of $O(n^2)$. Another advantage of updating B by its LDL^T factorization is that the positive definiteness of the quasi-Newton matrices can be easily preserved, namely, B_k is positive definite as long as all the elements of D_k are positive. Of course, the price that we have to pay is that this approach requires a more sophisticated and complicated programming.

Powell [74] proposed an update based on the symmetric decomposition of H_k . Assume that $H_k = Z_k Z_k^T$, where Z_k is a nonsingular matrix. If we have Z_k , the search direction $d_k = -H_k g_k$ can be obtained within $O(n^2)$ operations. Powell [74] applies BFGS formula to compute the factorization $Z_{k+1} Z_{k+1}^T$ of H_{k+1} . It is not difficult to find that the BFGS formula (16) can be written as

$$H_{k+1} = (I - s_k p_k^T) H_k (I - p_k s_k^T), \quad (89)$$

where

$$p_k = \frac{B_k s_k}{\sqrt{s_k^T y_k s_k^T B_k s_k}} + \frac{y_k}{s_k^T y_k}.$$

Thus, we can let

$$Z_{k+1} = (I - s_k p_k^T) Z_k Q_k, \quad (90)$$

with Q_k being any orthogonal matrix. Because $Z_k^T B_k Z_k = I$, the column vectors $z_k^{(i)}$ of Z_k are B_k -conjugate. Thus, Powell [74] selects orthogonal matrix Q_k such that the first column of $Z_k Q_k$ and s_k are the same direction. Let Q_k be an lower-Hessenberg matrix, then

$$(z_{k+1}^{(i)})^T G z_{k+1}^{(j)} = 0, \quad 1 \leq i \leq k < j \leq n, \quad (91)$$

for convex quadratic functions with exact line searches, where G is the Hessian matrix of the objective function. Owing to the conjugate property (91), we can see the quadratic termination of BFGS method.

Powell [74] also suggests a scaling technique for $z_{k+1}^{(i)}$. Assume that $Z_{k+1} = (z_{k+1}^{(1)}, \dots, z_{k+1}^{(n)})$ is already computed; we scale columns 2 to n in the following way

$$z_{k+1}^{(i)} := \max \left\{ 1, \frac{\sigma_k}{\|z_{k+1}^{(i)}\|_2} \right\} z_{k+1}^{(i)}, \quad (92)$$

where $\sigma_1 = \|z_2^{(1)}\|_2$ and $\sigma_k = \min\{\sigma_{k-1}, \|z_{k+1}^{(1)}\|_2\}$. The scaling operation does not alter the directions of $z_k^{(i)}$, thus the conjugate property (91) holds, which preserves the quadratic termination. However, the scaled matrix does not satisfy BFGS update formula, therefore for nonquadratic functions, it is not a BFGS method. And the convergence of this method is not analyzed for general nonlinear functions.

On the basis of Powell [74], Lalee and Nocedal [75] proposed the automatic column scaling BFGS method, which is proved to be global convergent and locally Q-superlinearly convergent for uniformly convex functions. Another extension of Powell's technique is given by Siegel [76].

NONLINEAR EQUATIONS AND NONLINEAR LEAST SQUARES

Quasi-Newton methods can also be applied to solve nonlinear equations and nonlinear least squares. Nonlinear equations are in the form:

$$F(x) = 0, \quad (93)$$

where $F(x) = (F_1(x), F_2(x), \dots, F_n(x))^T \in \mathbb{R}^n$. The quasi-Newton step d_k for Equation (93) can be obtained by solving

$$B_k d + F(x_k) = 0. \quad (94)$$

$B_k \in \mathbb{R}^{n \times n}$ is the quasi-Newton matrix, which approximates the Jacobian of $F(x)$. We require the quasi-Newton condition $B_{k+1} s_k = y_k$ where $s_k = x_{k+1} - x_k$ and $y_k = F(x_{k+1}) - F(x_k)$. Detailed discussions can be found in Refs 23, 29.

Nonlinear least square problems can be written in the form

$$\min \|F(x)\|_2^2, \quad (95)$$

where $F(x) = (F_1(x), F_2(x), \dots, F_m(x))^T \in \mathbb{R}^m$. Please notice here that m is not necessarily equal n . Let the Jacobian of $F(x)$ be $J(x)$. The Hessian matrix of $\frac{1}{2}\|F(x)\|_2^2$ is the sum of two terms, namely $J(x)^T J(x) + \sum_{i=1}^m F_i(x) \nabla^2 F_i(x)$. Hence we only need to apply the quasi-Newton technique to the second term as the first term is already known. A typical quasi-Newton method for nonlinear least squares, Equation (95) computes the search direction d_k by solving

$$(J(x_k)^T J(x_k) + B_k)d = -J(x_k)^T F(x_k), \quad (96)$$

where B_k is a quasi-Newton matrix. There are different quasi-Newton conditions. For example,

$$B_{k+1}s_k = (J(x_{k+1}) - J(x_k))^T F(x_{k+1}), \quad (97)$$

$$B_{k+1}s_k = J(x_{k+1})^T F(x_{k+1}) - J(x_k)^T F(x_k), \quad (98)$$

and

$$\begin{aligned} B_{k+1}s_k &= J(x_{k+1})^T F(x_{k+1}) - J(x_k)^T F(x_k) \\ &\quad - J(x_{k+1})^T J(x_{k+1})s_k \end{aligned} \quad (99)$$

are three possibilities. For more detailed discussions on quasi-Newton methods for nonlinear least squares problems, please see Refs 67, 77–79.

Pittsburgh, Pennsylvania

WHY SCHEDULING MATTERS

Try to remember the last time you asked yourself a question like this: “Why is this computer system so slow?” or “Why is it taking so long for the phone company to pick up my call?” At the time, you probably came to the realization that delay was being caused by *other users* who were sharing the database, or who were simultaneously using the call center.

Given that in many situations we do not have resources all to ourselves, one can ask, “How can we reduce user waiting time?” One obvious answer is to purchase more resources. For example, buying more RAM or a faster CPU could help in a computer system. Likewise, adding (human) servers could reduce waiting time at a call center. Such solutions, of course, cost money.

The goal of *scheduling* is to reduce mean delay *for free*! By simply serving jobs in the “right order,” we can often reduce mean delay by an order of magnitude, without requiring the purchase of additional resources. How can this be? What is the “right order” in which jobs should be scheduled? The answer depends on parameters of the system being scheduled, like load and the job size distribution. These parameters and others will be explained in the section titled “Queueing Model.” Typical scheduling policies will then be defined in the next section and analyzed in the section titled “Performance of Scheduling Policies in M/G/1.” Finally, in the section titled “Scheduling in Practice” we will see some recent real-world success stories where scheduling has been used to

greatly decrease average delays. The versatility of scheduling has made it the topic of thousands of research papers. While the majority of this article introduces scheduling under the simplest queueing model (an M/G/1 queue) and considers only the simplest performance metric (mean response time), in the last section we briefly discuss more complex queueing models, performance metrics, and scheduling policies, and give pointers to research papers covering those topics.

QUEUEING MODEL

Most of this article will deal with results of scheduling policies for a single queue, the M/G/1 queue, shown in Fig. 1. In the M/G/1 queue, it is assumed that jobs arrive according to a Poisson process with some average rate λ jobs per second. A “job” may refer to a computing job or may be a customer placing a call to a call center. We depict a job as a person in the figure. As shown in the figure, jobs are not all the same: some jobs have large size (require a large amount of service) and others have small size. For the M/G/1, it is assumed that all job sizes are independent instances from a common general job size distribution (‘G’ = general). We will use the random variable X to denote a job’s size. The expected (mean) job size is $\mathbf{E}[X]$, the second moment of job size is $\mathbf{E}[X^2]$, and the squared coefficient of variation of job size, C_X^2 , is the variance normalized by the square of the mean, namely,

$$C_X^2 = \frac{\text{var}(X)}{\mathbf{E}[X]^2}.$$

The *load*, ρ , of the system is the time-average fraction of the time that the server is busy, and is defined by $\rho = \lambda \mathbf{E}[X]$, where we assume $0 \leq \rho < 1$. In the analysis of scheduling policies, we will assume that the job size distribution is continuous with finite variance. We use $f(\cdot)$ to denote its probability density function (pdf) and $F(\cdot)$ to denote its cumulative distribution function.

Figure 1. Illustration of an M/G/1 queue. Jobs (or customers) have different sizes (service demands).

In many applications, particularly computer science applications, it is frequently the case that empirical job size distributions exhibit *very high variability*, and are best modeled by a Pareto, a lognormal, or a Weibull distribution, with high C_X^2 . Some examples include Unix process CPU requirements ([1,2], where C^2 values of 25 to 49 have been measured), sizes of files transferred through the Web [3,4], sizes of files stored in Unix file systems [5], durations of FTP transfers in the Internet [6], and CPU requirements for supercomputing jobs [7]. In this article we will therefore focus a lot of attention on the effect of job size variability. *Decreasing failure rate (DFR)* (hereafter referred to as DFR) is also prevalent in computer science applications. Roughly speaking, under DFR, the more service a job has received so far, the greater its remaining service requirement is likely to be. For example, the more CPU a UNIX job has used so far, the more CPU it is expected to use in the future [1], and the more bytes a flow has transmitted so far, the more bytes it is likely to transmit in the future [8].

DEFINITION OF COMMON SCHEDULING POLICIES

In this section, we define the most common scheduling policies for a single-server system. These can be subdivided along two axes (Table 1). *Blind* policies do not make use of a job's size when determining which job to run next, while *size-based* policies do. *Nonpreemptive* policies can not preempt a job once it has started running, while *preemptive* policies allow jobs to be stopped and restarted at a later point, without losing intermediary work. All policies which we consider are *work-conserving*, meaning that the server is always busy working on a job whenever there

Table 1. Taxonomy of some Common Scheduling Policies

	Non-preemptive	Preemptive
Blind to Size	FCFS RANDOM LCFS	PS PLCFS FB
Uses Size	SJF	PSJF SRPT

are jobs to be served, and no work that is done is lost.

We start by describing policies which are nonpreemptive and do not make use of a job's size:

FCFS or FIFO (First-Come-First-Served or First-In-First-Out). Jobs are served in the order that they arrive, with each job being run to completion before the next job receives service. This policy is typically used in manufacturing systems, call centers, and supercomputing centers. In such settings it is often difficult to preempt a running job, and it seems “fair” to serve customers in the order that they arrive.

RANDOM (Random-Order-Service). Whenever the server is free, it chooses a random job in the queue to run next and runs that job to completion. This policy is mostly of theoretical interest.

LCFS (Last-Come-First-Served; nonpreemptive). Whenever the server is free, it chooses the last job to arrive and runs that job to completion. This policy is used for applications where jobs are piled onto a “stack” structure, with each new job being “pushed” on top of the stack. When the server becomes free, it is convenient to “pop” the job off the top of the stack.

The following policies are preemptive and do not make use of a job's size:

PS (Processor-Sharing). Whenever there are n jobs in the system, each job is allocated $1/n$ th fraction of the server. PS has its roots in round-robin scheduling of computing jobs by the operating

system CPU, whereby the CPU rotates among the jobs in the queue in a cyclic fashion, giving each job only a small fixed quantum of service before moving on to the next job [9]. If one imagines the limit as the quantum size goes to zero, one gets PS. Besides its use in modeling CPU processing, PS scheduling is also a good model of equal bandwidth sharing of a network link.

PLCFS (Preemptive-Last-Come-First-Served). At every moment, the server is always running the job that arrived last. When a new jobs arrives, it always preempts the job in service. This policy makes sense, for example, in a market information processing situation, where the most recent job carries the most relevant information (current stock price) and older jobs are less relevant.

FB or LAS or SET (Foreground–Background also known as Least-Attained-Service or Shortest-Elapsed-Time). This policy always serves the job which has obtained the least service so far. We say that a job's *age* is the total service it has received so far. FB (LAS) always serves that job which has the lowest age, resulting in PS if all jobs have the same age. This policy is often used in situations where the job sizes are not known, but it is known that the job size distribution has DFR, for example in CPU scheduling or flow scheduling. Given unknown job size and DFR, serving the job with lowest age is equivalent to serving that job that has the lowest expected *remaining* service requirement. FB has been proven to minimize the mean response time and queue length distribution among blind policies [10].

We now move on to policies which make use of a job's size, favoring shorter jobs in some way. Given that typically the great majority of jobs are "short," favoring short jobs reduces overall mean response time (it is preferable to have long jobs wait behind short jobs, rather than the reverse).

SRPT (Shortest-Remaining-Processing-Time). This preemptive policy always runs that job which has the currently smallest remaining time. If a job arrives with shorter processing requirement than the job in service, then it preempts the job in service. SRPT is known to minimize the mean response time and the queue length [11], however its use is limited to situations where job size and remaining size are known.

PSJF (Preemptive-Shortest-Job-First). This preemptive policy is very similar to SRPT, but favors that job with smallest *original* size rather than smallest *remaining* size. This can be a useful substitute for SRPT when remaining size is not known.

SJF (Shortest-Job-First). Under this non-preemptive variant of PSJF, whenever the server becomes free, it always grabs the shortest job to work on (shortest original size). SJF is used in nonpreemptive settings, where one wants to get the benefit of favoring short jobs, but jobs can not be preempted.

PERFORMANCE OF SCHEDULING POLICIES IN M/G/1

The *response time* (a.k.a., flow time or sojourn time) of a job is the time from when a job arrives until it completes service, and is denoted by T . Since some scheduling policies might favor short jobs, it is also instructive to consider $T(x)$, the response time for a job conditioned on that job being of size x . In this section we state results on mean response time, $\mathbf{E}[T]$, and on $\mathbf{E}[T(x)]$ for an M/G/1 queue under the above scheduling policies. While we do not have room to prove these results, we will provide high-level intuition behind each formula. We refer the reader to Refs 12–14, where complete proofs of these results can be found.

While the formulas for the response time that we present below are all well-known, the comparative ranking between the different scheduling policies is not obvious

Figure 2. Mean response time as a function of load for the M/G/1 with various scheduling policies. The job size distribution is a Weibull with mean 1 and $C^2 = 10$.

Figure 3. Mean response time as a function of variability (C^2) for the M/G/1 with various scheduling policies. Load is fixed at $\rho = 0.7$. The job size distribution is a Weibull with fixed mean 1 and changing C^2 .

from the formulas, many of which include triple-nested integrals. We have therefore evaluated these formulas using MathematicaTM to compare the mean response time under the different policies as a function of load (Fig. 2) and as a function of C^2 (Fig. 3). In both figures, we assume a Weibull job size distribution. The Weibull, defined by

$\bar{F}(x) = e^{-\left(\frac{x}{\lambda}\right)^\alpha}$ with parameters λ and α , is convenient because when $\alpha < 1$, it has DFR and C^2 can be made as high as desired.

In the analysis below, we will require a few terms that we have not yet introduced. First, we will need to talk about the load made up of just those jobs of size $< x$. We will

denote this by

$$\rho(x) = \lambda \int_0^x tf(t) dt \quad (1)$$

Second, we will often talk about a *busy period*, which is defined to be the time from when a job arrives to an empty system until the system is once again empty. We use B to denote the length of a busy period in an M/G/1 queue (for any work-conserving policy), and $B(x)$ to denote the length of a busy period conditioned on the fact that the starting job is of size x . Then, it is well known [15] that the expected length of $B(x)$ and B increase with load ρ in the following way:

$$\mathbf{E}[B(x)] = \frac{x}{1-\rho}, \quad (2)$$

$$\mathbf{E}[B] = \frac{\mathbf{E}[X]}{1-\rho}. \quad (3)$$

First-Come-First-Served (FCFS)

A job's response time, T , under FCFS can be viewed as its *waiting time*, W (the time from when the job arrives until it first gets service) plus its service time, X . The mean waiting time is given by the well-known Pollaczek–Khinchin (P–K) formula:

$$\mathbf{E}[W]^{\text{FCFS}} = \frac{\lambda \mathbf{E}[X^2]}{2(1-\rho)}. \quad (4)$$

Of key importance in this formula is the variability of the job size distribution (the second moment term $\mathbf{E}[X^2]$). Specifically, even if the load, ρ , is low (say $\rho = \frac{1}{2}$), the mean waiting time can still be quite high if the second moment of the job size distribution is high.

The second moment term shows that mean delay (waiting time) is proportional to the variability of the job size distribution. This makes sense because when there are short jobs mixed in with long jobs, some short jobs will inevitably get stuck behind long jobs, causing large mean delay. Another way to think about Equation (4) is to consider the excess (remaining) service time on the job which is currently in service when a random arrival occurs. One might think that the expected excess for the job in service is $\frac{\mathbf{E}[X]}{2}$, however this is only true when jobs

have deterministic job sizes. When job sizes are variable, a random arrival is more likely to see a larger-than-average excess, and, in fact, by the Inspection Paradox [16], the expected excess turns out to be $\mathbf{E}[X^2]/2\mathbf{E}[X]$, which comes up in the derivation of formula (4) above.

From the mean waiting time, it is easy to derive the mean response time as follows:

$$\mathbf{E}[T(x)]^{\text{FCFS}} = x + \mathbf{E}[W]^{\text{FCFS}} = x + \frac{\lambda \mathbf{E}[X^2]}{2(1-\rho)}, \quad (5)$$

$$\begin{aligned} \mathbf{E}[T]^{\text{FCFS}} &= \mathbf{E}[X] + \mathbf{E}[W]^{\text{FCFS}} \\ &= \mathbf{E}[X] + \frac{\lambda \mathbf{E}[X^2]}{2(1-\rho)}. \end{aligned} \quad (6)$$

Looking at Figs 2 and 3, we see that mean response time under FCFS is worse than any of the other policies when $C^2 > 2$. This is because of the huge role that job size variability plays in response time.

RANDOM and Last-Come-First-Served (LCFS)

While RANDOM and LCFS seem very different from FCFS, it turns out that their mean response time is the same of that of FCFS, and thus they lie on top of FCFS in Figs 2 and 3. In fact, an even stronger claim can be made [14]:

Lemma 1. *For an M/G/1, any nonpreemptive scheduling policy that does not make use of job size will yield the same distribution on the number of jobs in the system.*

The above lemma is easy to understand: Although the different nonpreemptive policies may choose their next job differently at each completion point, the job is *not* chosen based on its size. Therefore the time until the next completion is equal in distribution under all such policies. Thus the number of arrivals between each completion is also stochastically the same across policies, resulting in the same stochastic process for the number of jobs in the system. It then follows by Little's Law [17] that the mean response time is

also the same for all such policies. Hence,

$$\begin{aligned}\mathbf{E}[T]^{\text{RANDOM}} &= \mathbf{E}[T]^{\text{LCFS}} = \mathbf{E}[T]^{\text{FCFS}} \\ &= \mathbf{E}[X] + \frac{\lambda \mathbf{E}[X^2]}{2(1-\rho)}.\end{aligned}\quad (7)$$

Note that although the distribution of the number of jobs in the system is the same for all blind nonpreemptive policies, the distribution of response time is not the same. In particular, it can be shown that [14]

$$\text{var}(T)^{\text{FCFS}} < \text{var}(T)^{\text{RANDOM}} < \text{var}(T)^{\text{LCFS}}.$$

Processor-Sharing (PS)

The PS policy has many pleasing properties. First, the distribution of the number of jobs in the M/G/1/PS turns out to be the same as in an M/M/1/FCFS queue [16]. Letting $\mathbf{E}[N]$ denote the mean number of jobs, we have that

$$\mathbf{E}[N]^{\text{PS}} = \frac{\rho}{1-\rho}.\quad (8)$$

The conditional mean response time for a job of size x is similarly attractive:

$$\mathbf{E}[T(x)]^{\text{PS}} = x/(1-\rho).\quad (9)$$

Another way of stating this is that, under PS, every job, regardless of its size, is slowed down by the same constant factor:

$$\begin{aligned}\text{Constant slowdown factor} &= \frac{\mathbf{E}[T(x)]^{\text{PS}}}{x} \\ &= \frac{1}{1-\rho}.\end{aligned}$$

Observe that $1/(1-\rho) = \mathbf{E}[N]^{\text{PS}} + 1$ (Eq. 8). Intuitively, it makes sense that an arrival is slowed down by a factor equal to the number of jobs it sees plus itself (roughly speaking).

Finally, from Equation (9), we see that

$$\mathbf{E}[T] = \frac{\mathbf{E}[X]}{1-\rho}.\quad (10)$$

This is fascinating because of its complete independence of the job size variability. This property is best illustrated by the perfectly horizontal line in Figure 3, showing the

insensitivity of mean response time to C^2 . The survey paper [18] presents more results on PS.

Preemptive-Last-Come-First-Served (PLCFS)

The PLCFS policy has surprisingly little to do with the LCFS policy, although they are both based on serving the last job to arrive. While the LCFS mean response time is highly affected by job size variability, we will see that the PLCFS mean response time is independent of job size variability.

Consider a new arrival of size x to an M/G/1/PLCFS queue. We will refer to this job as “job x .” All arrivals prior to job x will not get worked on while job x is in the system. However, all arrivals after job x , which occur before job x completes, will have priority over job x . Thus, we can view the response time of job x under PLCFS as the length of a busy period started by a job of size x , namely $B(x)$. From Equation (3), it follows that

$$\mathbf{E}[T(x)]^{\text{PLCFS}} = \frac{x}{1-\rho},\quad (11)$$

$$\mathbf{E}[T]^{\text{PLCFS}} = \frac{\mathbf{E}[X]}{1-\rho}.\quad (12)$$

Thus, the mean response time of the M/G/1/PLCFS is identical to that of the M/G/1/PS queue, in agreement with Figs 2 and 3. However PLCFS has an advantage over PS: typically many fewer preemptions. In fact, under PLCFS, each job creates at most two preemptions: one when the job arrives and one when it departs. Since preemptions are not free, this can be a real advantage.

Foreground–Background (FB) a.k.a. Least-Attained-Service (LAS)

Again consider an arrival of size x , which we refer to as “job x .” Under FB (a.k.a., LAS), the arriving job x immediately receives service (since it is the youngest job in the system). However, it may later have to share both with jobs already in the system and with new arrivals. Jobs in the system only affect job x *until they hit age x* , after which point they are invisible to job x . New arrivals while job x is

in the system will all initially have priority over job x , and will each get to complete *up to* x units of work (actually the minimum of x and their size) before job x leaves.

From the above observations, we can see that if $f(y)$ denotes the pdf for job size, then we need to define a new pdf $f_x(y)$ where jobs of size greater than x have been replaced by jobs of size x . We define

$$f_x(y) = \begin{cases} f(y), & y < x; \\ 1 - F(x), & y = x. \end{cases}$$

We define X_x to be a random variable with density function $f_x(y)$, and define $\rho_x = \lambda \mathbf{E}[X_x]$. Then, the expected response time for a job of size x is given by

$$\begin{aligned} \mathbf{E}[T(x)]^{\text{FB}} &= \frac{x + \frac{\frac{1}{2}\lambda \mathbf{E}[X_x^2]}{1 - \rho_x}}{1 - \rho_x} \\ &= \frac{x(1 - \rho_x) + \frac{1}{2}\lambda \mathbf{E}[X_x^2]}{(1 - \rho_x)^2}, \end{aligned} \quad (13)$$

$$\mathbf{E}[T]^{\text{FB}} = \int_0^\infty \mathbf{E}[T(x)] f(x) dx. \quad (14)$$

Observe that in appearance Equation (13) does not seem all that different from Equation (5), the corresponding equation for FCFS. There is still a dependence on the second moment of the job size distribution, however the job size is now X_x , with lots of extra mass on x and no mass above x . Also the result is scaled by $(1 - \rho_x)$, due to delay incurred by waiting on later-arriving jobs.

In practice, however, these small changes can have a large effect, particularly when the job size distribution has DFR. Figure 2 shows that the mean response time for FB can be quite close to that of SRPT, which is optimal, and quite far from FCFS. Furthermore, Fig. 3 shows that the mean response time for FB can actually decrease with increased job size variability, particularly when increased variability implies even stronger DFR behavior, as in the case of the Weibull job size distribution or the Pareto distribution. The survey paper [19] presents more results on FB.

As a final point, we note that the fact that the curves for FCFS, PS, and FB all

cross in Fig. 3 at the point where $C^2 = 1$ is no accident. For exponentially distributed job sizes ($C^2 = 1$), it is easy to argue that the continuous-time Markov chain tracking the number of jobs in the system is identical under all these policies.

Shortest-Job-First (SJF)

The waiting time for a job of size x under SJF is given below:

$$\mathbf{E}[W(x)]^{\text{SJF}} = \frac{\lambda \mathbf{E}[X^2]}{2(1 - \rho(x))^2}, \quad (15)$$

where $\rho(x)$, defined in Equation (1), denotes the load made up by jobs of size less than x only.

The sharp resemblance of the above formula to FCFS, (Eq. 4), may seem surprising but should not be. While SJF favors short jobs, even a short job still has to wait for the server to first free up. Thus, the waiting time for a job of size x , $\mathbf{E}[W(x)]^{\text{SJF}}$ still includes the excess term, involving $\mathbf{E}[X^2]$, that we saw in FCFS. The only difference is that now we have $(1 - \rho(x))^2$ in the denominator rather than $(1 - \rho)$. The intuition is as follows: When a job of size x arrives, it first has to wait for the server to finish serving its current job (the excess). Then job x has to wait behind those jobs in the queue whose size are $< x$ and these contribute a $(1 - \rho(x))$ factor in the denominator. Finally job x has to wait behind all future arrivals of size $< x$ during its waiting time—these contribute another $(1 - \rho(x))$ factor. Note that in FCFS, job x does not have to wait behind future arrivals.

The mean response time for SJF is given as follows:

$$\mathbf{E}[T(x)]^{\text{SJF}} = x + \mathbf{E}[W(x)]^{\text{SJF}}, \quad (16)$$

$$\mathbf{E}[T]^{\text{SJF}} = \mathbf{E}[X] + \int_0^\infty \mathbf{E}[W(x)]^{\text{SJF}} f(x) dx. \quad (17)$$

From Figs 2 and 3, we see that the performance of SJF is far worse than that of the other policies that favor short jobs (PSJF and SRPT), and in fact most closely resembles that of FCFS. This is because the $\mathbf{E}[X^2]$ term dominates mean response time in SJF, as

it does in FCFS. The second thing to notice is that SJF appears to “get better” as load gets high. This is because the $(1 - \rho(x))^2$ in the denominator depends on $\rho(x)$, which can be far lower than ρ , for high ρ , causing the denominator in SJF (even with its squared effect) to be larger than that in FCFS.

Preemptive-Shortest-Job-First (PSJF)

PSJF is the preemptive version of SJF. There are two components to an arrival’s response time: the time the arriving job waits until it *first* receives service (we call this *initial waiting time*), and the time from when the arrival first receives service until it completes (we call this *residence time*). Since a job in service can be preempted by smaller arrivals, a job’s residence time typically consists of way more than its service time. The mean response time for a job of size x is shown below:

$$\mathbf{E}[T(x)]^{\text{PSJF}} = \frac{\frac{\lambda}{2} \int_0^x t^2 f(t) dt}{(1 - \rho(x))^2} + \frac{x}{(1 - \rho(x))}. \quad (18)$$

The first term in Equation (18) indicates the initial waiting time for an arrival of size x . This is very similar in form to the waiting time for SJF. The key difference is that the $\mathbf{E}[X^2]$ term has been replaced by $\int_0^x t^2 f(t) dt$, which represents the contribution to the second moment made up only of jobs of size $< x$. To understand this change, observe that an arrival of size x no longer has to consider any jobs whose original size is $> x$, since the arrival has immediate priority over those jobs; this is in contrast to SJF, where a small arrival is still affected by the excess of the job in service, no matter what its size.

The second term above is the residence time for a job of size x . Observe that this has the form of the duration of an M/G/1 busy period, started by a job of size x , where the system load is $\rho(x)$ (Eq. 2). This should make perfect sense, since a job of size x starts its residence time when there are no jobs of size $< x$ in the system, however this job is then interrupted by every arrival of size $< x$, and cannot depart until there are again, no jobs of size $< x$ in the system.

The mean response time for PSJF is given as follows:

$$\mathbf{E}[T]^{\text{PSJF}} = \int_0^\infty \mathbf{E}[T(x)]^{\text{PSJF}} f(x) dx \quad (19)$$

As can be seen by Fig. 2, the mean response time under PSJF is far lower than that under SJF, simply because the $\mathbf{E}[X^2]$ factor is gone. As expected, Fig. 3 shows that PSJF is far less sensitive to variability in the job size distribution than is SJF.

Shortest-Remaining-Processing-Time (SRPT)

The mean response time for a job of size x under SRPT is very similar to that under PSJF, as shown below:

$$\mathbf{E}[T(x)]^{\text{SRPT}} = \frac{\frac{\lambda}{2} \int_0^x t^2 f(t) dt + \frac{\lambda}{2} x^2 (1 - F(x))}{(1 - \rho(x))^2} + \int_0^x \frac{dt}{1 - \rho(t)} \quad (20)$$

The first term represents the initial waiting time for a job of size x . The only difference from PSJF is the additional term involving $x^2(1 - F(x))$. To get a rough feel for where this term comes from, observe that under SRPT, jobs of size $> x$ can still contribute to the waiting time of an arrival of size x , if those jobs of size $> x$ have remaining time $\leq x$ at the time job x arrives. Thus the $(1 - F(x))$ fraction of jobs of original size $> x$ can contribute at most x^2 to the second moment portion of the initial waiting time of job x .

The second term represents the residence time for a job of size x . This again resembles the residence time for PSJF, however it is actually a lot smaller. The point is that, as the remaining size of job x drops, the job has to compete with fewer and fewer interruptions (less load), because only those jobs with lower remaining size can bother it. Thus, the residence time for a job of size x can actually be viewed as a sum of busy periods, each started by a job of size dt , where each successive busy period fights against less and less load.

As expected from Ref. 11, Fig. 2 shows that the mean response time under SRPT is superior to all other policies. Also as seen in

Fig. 3, the response time actually decreases slightly with increased variability. Importantly, PSJF (with its lower initial waiting time and higher residence time) is a very close approximation to SRPT with respect to overall mean response time.

SCHEDULING IN PRACTICE

It is clear from Figs 2 and 3 that the choice of scheduling policy can dramatically affect mean response time. In situations where the job size variability is high, preemptive policies can be orders of magnitude more effective than nonpreemptive policies. When load and variability are high (e.g., $\rho = 0.9$ and $C^2 = 10$, as shown in Fig. 2), there is also significant differentiation among preemptive policies; for instance, SRPT offers more than a three-fold improvement over PS.

These dramatic improvements, at the cost of no additional resources, have not been lost on the computer systems community, which has incorporated smart scheduling in a wide variety of applications including web servers [20], routers [21], wireless networks [22], operating systems [23], and many more. Below we elaborate on just two such examples:

In a series of papers [20,24,25], Harchol-Balter *et al.* look at the problem of speeding up the mean response time in retrieving files at a web server. They find that the bottleneck resource for static “Get FILE” requests is the limited bandwidth in the web server’s access link. Traditionally, all requests share this bandwidth fairly in a manner resembling PS scheduling. The authors argue that scheduling requests in SRPT order would decrease mean response time, since file sizes at web sites are known to exhibit highly variable Pareto distributions. However, there are two potential stumbling blocks to implementing SRPT scheduling at web servers: first, one needs to know the “size” of the jobs. Second, there is a fear that by favoring short jobs, one might “starve” long jobs, or certainly treat them very unfairly. The authors deal with the first stumbling block by showing that the “size” of a job, in this case the time to retrieve a file, is well-approximated by the size of the

file, which is known. The authors deal with the starvation issue in Refs 26 and 27, where they prove a counterintuitive theorem, showing that, when job sizes follow a heavy-tailed distribution (like the Pareto or Bounded-Pareto), the expected response time of *every* job (including the largest-size job) is actually smaller under SRPT than under PS, provided load is not too high. Motivated by this “all-can-win” fairness result, the authors in Ref. 20 proceed to implement SRPT scheduling of HTTP requests by modifying the Linux kernel of an Apache web server to change the order that the server’s socket buffers are drained into the server’s access link, in accordance with SRPT scheduling. They demonstrate that this change improves mean response time by a factor of 5 for higher load, without penalizing requests for large files.

Similarly, Biersack *et al.* (see Ref. 8 and the references therein) consider flow scheduling at a bottleneck router, again with the goal of minimizing mean response time. However here the problem is complicated by the fact that the flow durations are not known *a priori*, so it is not possible to bias toward “short” flows (flows with few packets). Biersack *et al.* reason that since flow durations have a Pareto distribution (with DFR), favoring “young” flows is a good approximation to favoring “short” flows. They implement an FB-like policy which favors those flows which have transmitted the fewest packets so far, demonstrating an order of magnitude improvement over the traditional PS scheduling of flows. However, there are fairness issues with FB that are not present in SRPT, which they resolve by further tailoring of their FB policy.

OTHER TOPICS IN SCHEDULING AND REFERENCES

This document has offered a very brief introduction to scheduling in the M/G/1 queue. However, what is presented here is just the tip of the iceberg in terms of what is known about scheduling.

First of all, this document only considers mean response time. In fact, the full Laplace

transform of response time (and thus higher moments of response time) is known for all the policies discussed herein and is usually almost as easy to derive [13,14], although the high-level intuition is less easy to see from the transform. The tail behavior of response time has also been studied for many policies (see the survey in Ref. 28). For example, it is known that for heavy-tailed job size distributions, the response time tails for SRPT, PS, FB, and PLCFs all mimic the tail of the job size distribution, whereas the response time tails for FCFS and SJF mimic the tail of the excess of the job size distribution. Other performance metrics, like “fairness,” have also recently become very important in computer systems (see Refs 27 and 29 for an overview).

There are many scheduling policies which we do not have room to mention; in particular, there are many variants of PS that come up in networking (see the survey in Ref. 30). We also have not had room to delve into multiclass queues, where each class i of jobs has its own arrival rate λ_i and its own job size distribution, F_i , and jobs in one class might have preemptive, or nonpreemptive, priority over another class [15]. Also, while we have studied individual policies in this paper, there is a growing body of work that deals with broad classes of scheduling policies. In particular, the SMART class was introduced in Ref. 31 and defined so as to encompass a wide range of policies which favor short jobs.

Scheduling theory also exists for architectures far more general than the M/G/1 queue. Many computer systems follow a closed-loop architecture, where there is a fixed number of jobs, N , and a new job creation is only triggered by a job completion. The impact of scheduling in closed-loop systems has been shown to be far smaller than that in the open systems we have considered thus far [32]. By contrast, scheduling can have a huge impact in server farm architectures (multiserver systems); see Ref. 33, where scheduling decisions need to be made both at the central router level and at the individual host level. Lastly, fluctuations in load, for example alternations between very high and low load, can also greatly intensify the effect of scheduling, as seen in Refs 25 and 34.

Finally, while everything we have mentioned so far involves a stochastic setting, there is an entire field of on-line scheduling where the metric is worst-case response time and policies are ranked according to their “competitive ratio” when compared with the optimal policy (see the survey paper [35]).

QUEUEING NOTATION

ROBERT B. COOPER
Department of Computer
Science and Engineering,
Florida Atlantic University,
Boca Raton, Florida

Queueing theory is concerned with the mathematical analysis of systems that provide service to random demands. This theory has many application areas (e.g., industrial engineering, electrical engineering, computer science, telecommunications, and operations management). Consequently, the terminology and notation, while often intuitively sensible, are not always consistent. The mathematical theory is focused on simple (but meaningful) mathematical models that can be described in the precise terminology required for mathematical analysis. In this article, we give an overview of the notation and terminology used in describing the standard basic queueing models.

In the basic queueing model, “customers” arrive (to request service), wait (if necessary) for a “server” to become available to provide the required service, and then leave. Thus the model consists of three components: (i) the (stochastic) arrival process, (ii) the (stochastic) service requirement, and (iii) the physical configuration of the servers and their operating rules. The objective of the theory is to understand the relationship between these components and the behavior (performance measures) of the system.

In a now-classic 1953 paper, D.G. Kendall [1] proposed the following notation to describe a queueing model: $a/b/c$, where a describes the input (arrival) process, b describes the service process, and c is the number of servers. Implicit in this description is the assumption that each arriving customer is assigned to a server immediately if one is available and holds that server for the length of time required (the “service time”); if a server is not immediately available, the customer waits

in an infinite-capacity queue (or waiting room). Furthermore, the servers are all identical, and the waiting customers are served according to the FIFO (first in, first out) “queue discipline” (although the queue discipline might have no effect on the values of any particular performance measure, and therefore its omission from the explicit notation might be irrelevant).

Kendall’s notation is now widely used to describe queueing models. But, clearly, there are an infinite number of possible physical configurations, operating protocols, queue disciplines, and so on, with the consequence that sometimes authors extend this notation to include those variations; that is, they treat Kendall’s scheme as an algorithm that can be decoded to describe a particular model, rather than as a descriptive name of that model. For example, $a/b/c/n$ might be used to indicate that the model has a capacity of n customers, or that there are n different sources that generate the arrivals (see *Finite Population Models—Single Station Queues*), and so on. It has become commonplace to extend Kendall’s original three-symbol description to longer strings, such as $a/b/c/d/e$, where d is some measure of system capacity and e is the queue discipline. (However, sometimes even longer strings are used; clearly, this can get out of hand.) Besides FIFO, other queue disciplines include LIFO (last in, first out), LIFO-PR (last in, first out, preemptive-resume), SIRO (service in random order), SPTF (shortest processing time first), SRPT (shortest remaining processing time first), RR (round robin), PS (processor sharing), VAC (server vacations), and others. If, in any particular case, one wants to introduce Kendall-like notation to describe a particular model, then the shorthand notation should be described upfront, rather than assuming that the reader can decode its meaning; similarly, the reader should be careful in interpreting the meaning of any such notation without first ascertaining exactly what the model is. With this caveat, we describe Kendall’s notation.

Here are the conventions:

G	general (no particular assumption)
GI	general independent (the random variables in question are mutually independent and identically distributed)
M	Markov or memoryless (exponential random variables)
D	deterministic (the same constant value for each realization of the random variable)
E_k	k -phase Erlangian (sum of k independent, identical, exponentially distributed “phases”)
PH	phase-type (sum of a (possibly random) number of independent, exponentially distributed phases)
MAP	Markovian arrival process
$BMAP$	batch Markovian arrival process

Then, for example, a typical (and most important) model is $M/G/1$ (see **The $M/G/1$ Queue**). This describes a model with Poisson input (M denotes independent, identically distributed, exponential interarrival times), General service times, and 1 server. It is usually assumed implicitly that the service times are independent of each other (hence, $M/GI/1$ would be more appropriate, but is rarely used, although renewal-process input is often denoted explicitly, as in $GI/M/1$), and independent of the arrival process. It is also implicitly assumed here that there is infinite queueing capacity (so that no customer is ever “cleared” from the system because of lack of waiting space) and that the customers are served in FIFO order (although, depending on the performance measure of interest, the queue discipline might have no effect). The fact that the service times here are General means that the formulas that describe the behavior of $M/G/1$ are to be evaluated using the distribution function of the service times as if it were a parameter. (Thus, $M/M/1$ and $M/D/1$ are important special cases.) For $M/G/1$, the celebrated Pollaczek–Khintchine formula relates the mean waiting time to the utilization of the server (typically denoted by ρ) and to the

mean and variance of the distribution of service times.

Another important example is $M/G/s/s$ (see **The $M/G/s/s$ Queue**). Here, the second s specifies that the capacity of the system is s , which is the same as the number of servers; that is, in this model any customer who finds all servers busy does not wait, but is immediately cleared from the system. In a sense, this is not a queueing model, because there is no queue (unless one considers the customers in service to be part of the queue, which is a common convention). Some representations for the case of Poisson input and $n > 0$ waiting positions might be $M/G/s/n$, $M/G/s/s + n$, or $M/G/s + n$, all indicating s servers and n waiting positions, for a total system capacity of $s + n$, and, in the infinite-capacity case, the default notation $M/G/s$. Another example is $M^x/G/1$, say, in which the customers arrive in batches of size X (which may be a random variable), and the arrival times of the batches follow a Poisson process (see **Batch Arrivals and Service—Single Station Queues**). The point is that Kendall’s notation provides a convenient shorthand for describing queueing models, but the reader should be alert to avoid incorrect interpretations. With this background, most of the basic queueing models are now completely specified.

The notations PH , MAP , and $BMAP$ refer to generalizations of the method of phases, where the key idea is to model random time intervals as composed of a (possibly random) number of exponentially distributed phases and then to exploit the simplifications arising from the resulting Markovian structure (see **Matrix Analytic Method: Overview and History**).

The important model $M/G/s/s$ (s servers and 0 waiting positions) is often called the *Erlang B model* or the *Erlang loss model* (because customers who find all servers busy are cleared from the system and thus are lost). The formula that describes the probability of loss (the fraction of arriving customers who are cleared from the system) is typically called the *Erlang B formula* or *Erlang’s first formula*. Likewise, the important model $M/M/s$ (or, $M/M/s/\infty$, s servers and infinite waiting capacity) is typically called the *Erlang C model* or the *Erlang delay model*,

and the formula that describes the probability that an arriving customer will be forced to wait until a server becomes available is often called the *Erlang C formula* or *Erlang's second formula* (see **The M/M/s Queue**). The Erlang B and Erlang C formulas were first published in 1917 by A.K. Erlang. The context was telephone traffic (teletraffic) theory and engineering, and the terminology reflects this. The "B" in Erlang B refers to Blocking; a call is blocked if it finds all servers busy (but beware, there is not a universally accepted definition of "blocked"), in which case "lost calls are cleared." In the early teletraffic literature, the $M/G/\infty$ model is called *lost calls held*; this can be interpreted to say that the calls leave the system at the same rate whether they are in service or are waiting in the queue. (Aficionados should see Brockmeyer *et al.* [2] for reprints of Erlang's papers and interesting historical and biographical material. Syski [3] gives an invaluable authoritative and comprehensive treatment of teletraffic theory prior to 1960.) This model is now often called *Erlang A* (for Abandonment), generalizations of which can be used to describe systems (like the ubiquitous call center) in which customers renege or depart from the queue before entering service. In this context, the Kendall notation $a/b/s + M$, for example, would indicate that there are s servers and an infinite-capacity waiting room from which customers abandon after waiting an exponentially (M) distributed length of time (but beware, this could be interpreted to describe an s -server system with a waiting room of capacity M).

Two of the most important theorems in queueing theory are Little's Law [4] (see **Little's Law and Related Results**) and PASTA [5] (see **PASTA and Related Results**). Little's Law expresses the equality $L = \lambda W$, where L stands for expected number of customers in the "system," W stands for expected time spent by a customer in the system, and λ is the rate at which the customers enter the system. Originally, L denoted queue Length, W denoted Waiting time in queue, and λ denoted the customer arrival rate, but these

definitions are very flexible as long as one is consistent in the definition of "system." Little's Law is notable for its great generality; all that is required of L , λ , and W is, essentially, their existence.

PASTA is an acronym for Poisson Arrivals See Time Averages. In essence, it expresses the fact that if the customers arrive according to a Poisson process, then the states of the system that they observe at (just prior to) their arrival epochs (in the queueing theory vernacular, "epoch" means "instant") has the same distribution as the states observed at random epochs or averaged over time. PASTA is notable for its utility in solving queueing models (one can shift one's viewpoint as is convenient) and for its counterintuitive subtlety.

In summary, queueing theory is vast and, because of its many various application areas, its notation, while usually intuitive, is not always consistent across application areas. Finally, it is interesting and amusing to observe that almost all books and most technical journals use the spelling "queueing," which makes it the only (ordinary) word in the English language with five successive vowels, whereas virtually all spell-checkers and nontechnical editors (in the United States) omit the second E.

R&D RISK MANAGEMENT

JAMES C. FELLI
Drug Disposition, Eli Lilly & Company,
Indianapolis, Indiana

JOHN S. ANDERSEN
Decision Sciences, Eli Lilly & Company,
Indianapolis, Indiana

RISK

Risk is a major concern in functional R&D organizations. It can arise from any number of sources, such as from accidents to misunderstandings to natural disasters. Yet, despite its importance and pervasiveness, it is no small feat to find a common understanding of “risk” within or across a firm’s R&D functions, let alone across industries.

The general concepts of risk and peoples’ attitudes toward risk have long held prominent places in game theory, decision analysis, and economics, and have been scrutinized using a wide range of methods from puzzles and games to prospect and utility theory [1–5]. It should come as no surprise that these concepts have attracted particular attention in the financial arena. In this setting, Holton provides an interesting discussion of the foundations of risk by exploring the relationship between risk, uncertainty, and exposure [6]. Of particular interest in business settings—and especially in R&D—are risks derived from perceptual and motivational biases, most notably optimism and personal desire [7–10]. Also noteworthy are project-related risks assumed either explicitly or implicitly as a consequence of forecast inaccuracies arising from technical, psychological, and political–economic interpretations [11].

Despite a rich history of exploration and scrutiny, the word “risk” has managed to maintain a slippery meaning. The International Organization for Standardization (ISO) has published standards on terminology and guidelines for risk management,

defining “risk” to be “the effect of uncertainty on objectives.” Despite this attempt at standardization, the term is persistently used by different people at different times to mean different things [12,13]. To a pharmaceutical discovery scientist, a “risky project” may be one with low technical feasibility. To an aerospace project manager, it may be a project that is likely to accrue large cost overruns on its way to certain completion. A “risky project” to a toy company might be one that is readily designed, developed, and manufactured but faces questionable potential for commercial success. The scientist, the manager and the executive are all articulate concern about uncertainty consistent with the high-level ISO definition, but focus on different types of uncertainty with different, predominantly negative consequences.

To an R&D organization, risk is about uncertainty and unwantedness. It is more than simply a measure of the likelihood of the obtainment of some unwanted event; it also carries with it some consideration of the attendant consequences of that event. For early stage R&D projects, tasks are undertaken to demonstrate feasibility. The obvious unwanted outcome is failure to do so, and the attendant consequence is that the money spent on the project is no longer available to be spent on other projects. As a project advances through the R&D process, from concept to product, the factors contributing to risk become more varied as the consequences become more numerous. A product may pass a critical technical success hurdle only to run the “risk of missing a launch deadline.” Or a product may clear its launch hurdle, but run the “risk of failing in the marketplace.”

Given such diversity and dynamics, it is easy to see why the cogent characterization and discussion of risk presents such great difficulty to R&D organizations. As a consequence, these organizations typically respond by implementing programs designed to highlight and dynamically manage a portfolio of risks throughout the R&D process stream.

RISK MANAGEMENT

Risk management is the general term for the collection of formal processes employed by R&D organizations to understand and mitigate risks during the development process. The fundamental steps involved include characterization of risk factors, monitoring of risk factors, and mitigation of risk factors. The risk analysis community generally considers the process of risk analysis to include both risk assessment and management.

A risk factor is anything that might proximately affect or directly cause the occurrence of an unwanted event, such as a delay in a development timeline. In terms of the ISO definition, a risk factor may be considered to be any uncertain event that might directly contribute to a negative “effect on objectives.” [13] The distinction between risks and risk factors is one of scope. For example, given a focus on minimizing the risk of a budget overrun, a project manager would consider all relevant factors that could reasonably affect the likelihood and/or magnitude of a budget overrun. Each of these factors, in turn, may be a fundamental risk from another perspective, with its own set of constituent factors. The distinction between risks and risk factors helps functional managers set operational objectives against those risks for which they will be held accountable and appropriately allocate resources to mitigate the underlying factors within their sphere of influence or control. Once identified, relevant risk factors can be prioritized to inform additional resource allocation decisions for their monitoring and mitigation. Given a well-defined risk factor with sufficient lead time to respond, most R&D organizations are able to enact robust sets of activities to assuage the consequences of its realization. In addition, an organization may engage in separate activities to influence either the likelihood or the consequences of specific risk factors.

Conventional risk management approaches tend to separate risk into schedule, cost, and performance risk [14], typically defining risk as a measure of the likelihood of not meeting a critical timeline, exceeding a fixed budget, or falling short of a performance benchmark. Several operational research

methods and models are commonly applied to characterize the consequences of specific sets of risk factors. These include, but are not limited to traditional and stochastic PERT/CPM [15] and critical chain [16] to quantify the likelihood and extent of project cost and timeline overruns; queueing models to investigate risk factors derived from the flow of information and materials [17]; inventory models to understand supply chain risks consequent to product and material stockouts [18]; mathematical and dynamic programming to optimize designs and processes [19]; and simulation modeling to investigate system and market behavior due to intrinsic and extrinsic uncertainties [20]. While a plethora of stand-alone or add-in software packages exist to help managers unleash the power of these models as part of their risk management arsenal, R&D organizations must also appropriately invest in personnel development and training to properly interpret and leverage their use.

Despite the sophisticated analytical tools available, many R&D organizations struggle with risk assessment and management. Their fundamental challenge is their inability to appropriately identify, characterize, and monitor relevant risk factors. This challenge is compounded when an organization suspects there are risk factors that it is unable to articulate, either due to lack of proximity, understanding, or experience. For example, an R&D organization may deal with a new partner to complete some work and may not have sufficient knowledge of the partner to appropriately gauge how the partner’s risk factors might translate into risks for the organization. Of particular consequence are risk factors that derive from cultural differences.

The characterization of a risk factor is typically accomplished by consideration of the various events that could cause it to manifest. The R&D organization must carefully define the risk factor to appropriately estimate its likelihood of manifestation and the consequences faced by the organization given its manifestation. Specifically, what exactly is the unwanted event, and how unwanted is it? Framing effect and motivation biases often interfere with these

tasks, as do the evaluation heuristics of availability and anchoring-and-adjustment [21]. These limitations to rationality may cause some risk factors to be ignored and others to be inappropriately characterized in terms of likelihood of occurrence or magnitude of effect. The combined effects of availability and anchoring-and-adjusting can be particularly troublesome in cases where one not only inadvertently bases one's assessment of an event's likelihood on memory rather than complete data (availability), but also inadequately captures the range of the event's potential consequences due to insufficient adjustment from its baseline outcome (anchoring-and-adjustment).

Some risk factors manifest slowly over time and may be preceded by clear signals (e.g., changes in the political environment) whereas others may be sudden and unexpected (e.g., a destructive fire at a supplier's manufacturing facility). Monitoring the set of identified risk factors costs the R&D organization time and money that cannot be invested in developing products. What should the organization monitor? How closely? If data are collected, how is the collection accomplished? With what frequency are the data refreshed? Who holds the data within the organization? These are all questions with potentially profound resource implications.

The management of risks in an R&D organization is typically accomplished through the creation and conditional execution of formal risk mitigation plans. Risk mitigation plans are typically triggered by a predefined event (e.g., a report of a risk factor obtaining). These plans define the organization's response to specific events and detail resource expenditures and actions of employees to lessen or counteract the consequences of the realized risk factor. Some industrial practices and/or policies require firms to maintain risk mitigation plans. Some firms have learned the hard way that risk mitigation plans are very valuable to mitigate well-understood risks in risky enterprises.

Risk mitigation plans require an organization to explicitly consider four things: risk factor characterization, risk factor likelihood,

risk factor consequence, and consequence alleviation or resolution.

RISK CHARACTERIZATION

While it seems obvious that risk factors should be understood in terms of both likelihood and consequence, it is less obvious but critically important to understand the context in their characterization. When one R&D manager describes a project as "risky," what exactly does the manager mean? Many problems in an R&D organization arise from people agreeing that a project is "risky" and then walking away with different action plans due to different perceptions of what "risky" actually means to them.

The general idea of risk can be decomposed into general contextual categories. An example is presented in Fig. 1, where the categories are technical risk, commercial risk, and execution risk. Execution risk is further decomposed into timeline risk and cost risk.

Technical Risk. This encapsulates the traditional idea of "probability of technical success" in terms of meeting a specific set of goals (e.g., manufacturing feasibility, efficacy and safety expectations, reliability commitments). The fundamental question is "can we do this project and accomplish these ends?" This is frequently presented as a binary outcome event to decision makers: yes or no, success or failure.

Commercial Risk. This presumes that the technical risk has been resolved and that

Figure 1. A composite model of risk for R&D management.

development can be accomplished. The focus here is on the subsequent commercial impact of the project or product. Will the product meet the market needs? How well will it do upon commercialization? This is most often addressed via scenario planning using financial metrics such as net present value (NPV).

Execution Risk. Execution risk focuses on the consequences of uncertainty in the successful completion of a project in accordance with its formal project plan. Given a project plan, the two principal metrics of interest to project managers and R&D executives are compliance with budget and adherence to timeline. Both of these are critical to R&D organizations pursuing multiple, simultaneous projects. Money spent on one project cannot be spent on another, while timelines drive allocations of resources, people and material. Where technical risk asks whether a project can be successfully completed, execution risk asks whether success can be secured on time and on budget.

This definition of risk as a composite measure of more well-defined, context-specific risks facilitates understanding and communication across R&D functions. Clear understanding flows from precise definitions of specific risk factors within the context of each category. This decomposition of risk facilitates clearer understanding of and metrics for the monitoring and characterization of risk factors. It additionally facilitates more focused and productive discussion among typically nontechnical managers and senior decision makers.

The risk decomposition illustrated in Fig. 1 is appropriate for a commercial R&D organization. Different categories may be appropriate for noncommercial organizations. For example, a military R&D organization may find it beneficial to decompose risk into technical, interoperability, and execution risks. A governmental agency may consider political risk to be an appropriate category.

Even within these risk components, we must carefully define what we mean by “risk.” It is here that we consider, in each context, what underlying elements are both uncertain and unwanted. Note that neither attribute

alone is sufficient. Pure association of risk with probability ignores consequence; pure association of risk with consequence ignores likelihood. To truly appreciate risk, we must consider both: how likely is an unwanted event to obtain, and what are the consequences if it does?

PROBABILITY AND CONSEQUENCE

For discussion purposes, Fig. 2 is a useful construct for the joint consideration of probability and consequence. Decision makers typically consider situations to present “low risk” if they are characterized by a low likelihood of occurrence and small potential consequence. Similarly, situations bearing a high chance of occurrence and great potential consequence are typically perceived as “high risk.” “Low-risk” situations typically receive low levels mitigation planning, whereas “high-risk” situations generally enjoy rich, detailed mitigation planning. In practice, likelihood-consequence tables akin to that in Fig. 2, but with more refinement in each dimension, are widely used to screen risks.

In a resource constrained environment, loosely regulated firms may opt to categorize situations of high probability and low consequence as “low risk” and treat them accordingly. Regulated firms, however, do not generally enjoy such discretion. For regulated firms, events with a high likelihood of obtainment and/or the potential for severe consequences (e.g., drug development, nuclear

Potential consequence	High	?	High risk
	Low	Low risk	?
		Low	High
		Probability of obtainment	

Figure 2. Example of a likelihood-consequence table to define risk.

reactor construction) typically require formal mitigation plans to assure regulatory compliance at prescribed points throughout a product's development and life cycle. In most cases, events characterized by low likelihood and great consequence require, at a minimum, thoughtful analysis. In such cases, it is important to understand the distribution of the potential consequence.

A PROJECT-LEVEL EXAMPLE: COST RISK

With today's readily available desktop simulation tools, R&D managers have the ability to simulate various project plans to generate plausible distributions for time and cost. While this effort requires time and cost distributions on component activities, it also affords the manager the opportunity to bring together different stakeholders for formal and structured discussion. This activity alone can often reveal important insights critical for appropriate modeling of uncertainty.

Consider the case of a manager who must set a budget for a project with the total cost density given in Fig. 3, where $C_{\min}$, $E[C]$, and $C_{\max}$ represent the project's minimum, expected, and maximum cost. The seemingly obvious solution is to set the budget at the project's expected cost, $E[C]$. In doing so, however, the manager must accept a significant probability of a budget overrun in the range of 0 to $C_{\max} - E[C]$. If the manager elects to set the budget at a higher level, C^* , for instance, both the likelihood and range of a budget overrun decrease, but the marginal budget increase $C^* - E[C]$ now represents funding no longer available to other projects.

To put some concrete numbers on this example, suppose that $f(C) \sim \text{Beta}(2,6)$ over $C_{\min} = \$100\text{M}$ and $C_{\max} = \$300\text{M}$. Given this density, $E[C] = \$250\text{M}$. If the manager sets the project budget at $E[C]$, there is a 56% chance that the project will go over budget. In fact, the expected budget overrun is \$11.75 M. If the manager sets the budget at $C^* = \$258\text{M}$, the chance of a budget overrun falls to 45% and the expected budget overrun drops to \$7.65 M. Clearly, setting the project budget equal to its expected cost presents a greater "risk" of a budget overrun, but is it worth an additional \$8 M increase to reduce the expected budget overrun by \$4.1 M? What else could have been done with \$8 M? These are the critical questions for management.

RISK AND OPPORTUNITY

Risk and opportunity are matters of perspective. Consider an investment with an expected return of 10%. The possibility of a return in excess of 10% is typically perceived as an opportunity for additional gain, whereas the possibility of a return less than 10% is typically perceived as a risk of insufficient gain. The intrinsic uncertainty in the investment's return is what it is; however, the potential investor's perspective, rooted in reference points (e.g., 10%) and objectives (e.g., maximize return), will ultimately determine whether it represents a risk to be avoided or an opportunity to be embraced. G. K. Chesterton summed this duality up nicely:

'An adventure is only an inconvenience rightly considered. An inconvenience is only an adventure wrongly considered.'

Figure 3. Density of total project cost for a hypothetical R&D project.

Given an appropriate scoring system, any R&D endeavor can be scored against a scale partitioned into two regions: “unwanted” and “wanted.” In monetary terms, we typically equate “losses” with “unwanted” and “gains” with “wanted.” Let the reference point r designate the boundary between “unwanted” and “wanted” values on this scale, and define the functions g and f to represent the cumulative and inverse cumulative distributions of the uncertain payoff a for a hypothetical project A. That is, for some benchmark α , $g(\alpha) = P[a < \alpha]$ and $f(\alpha) = P[a > \alpha]$. We can now calculate the expected loss and expected opportunity of project A. Define the quantities $a_0 = E[a|“unwanted”]$ and $a^0 = E[a|“wanted”]$. The “expected unwantedness” of project A is $a_0 g(r)$ and the “expected wantedness” of project A is $a^0 f(r)$. This “expected unwantedness” takes into account both likelihood and consequence and makes for a natural measure of “risk” in terms of the underlying scale. Similarly, “expected wantedness” can be thought of as an expression of “opportunity.”

INTEGRATED PROJECT RISK

From a project perspective, an integrated view of the risks noted in Fig. 1 can be of great value to a decision maker. One such

view for a hypothetical R&D project is provided in Fig. 4.

The number in the upper right corner of Fig. 4 quantifies the technical uncertainty surrounding the project. At the time of figure creation, there was a 65% chance that the project would be successfully developed and deployed. Successful development presumes that the project will not only be completed, but will also meet a specific set of performance targets upon completion (e.g., safety, reliability). The heavy line characterizes the project timeline uncertainty given successful completion. The choice of using the cumulative versus inverse cumulative distribution over launch date is matter of taste. We have found it more useful to frame timeline risk discussions with managers in terms of failing to launch by a given date as opposed to launching some time prior to a given date, and have therefore used an inverse cumulative distribution in Fig. 4. The small distributions over various parts of the inverse distribution in Fig. 4 are the distributions of the NPV at specific launch dates. The launch date and expected NPV are noted to the right of each distribution; the NPV range is noted below the distribution. The expected NPV is also indicated by a point on the axis. For example, given technical success and a product launch in March 2014, the expected NPV

Figure 4. An example of an integrated risk view for a hypothetical R&D project.

of the project is \$902 M with a range of \$712 M to \$1.12B. Note the large drop in NPV for an August 2014 launch date. This may represent a situation in which a competitor has launched a rival product between March 2014 and August 2014.

This integrated risk picture provides information on three key aspects of project risk:

1. the likelihood that the project will be successfully completed,
2. the likelihood that a specific launch date will be met, and
3. the net monetary consequences associated with specific launch dates.

Taken together, these insights help R&D managers consider changes in plans to affect costs, timelines, and probabilities of technical success, either through or in addition to formal risk mitigation plans.

One may be tempted at this point to combine these aspects of project risk into a single distribution over project NPV. Although of great potential value to project and portfolio managers alike, such a construct would require a staggering amount of effort to produce. Most organizations partition their workforce into specialized functions (e.g., marketing, finance, project management); consequently, the information required to generate a single NPV distribution is typically fragmented across several functions. Collecting and integrating that information into a meaningful distribution requires functional cooperation, political alignment, and reconciling both data formatting diversity and modeling discrepancies. In addition, the cost and revenue streams associated with a new product launch typically exhibit sensitivity to time frames: the NPV of a product launch delayed by two years is rarely equal to the NPV calculated by simply sliding the cost and revenue streams out two years.

PORTFOLIO-LEVEL RISK

Careful consideration of project-level risk across all projects in an R&D pipeline can provide insight into portfolio-level risks not

typically appreciated on a project level. This is a “bottom-up” approach to portfolio risk. Each project’s risk is characterized by the process outlined above and common risks across several projects are identified. For example, suppose that several project teams have identified timeline uncertainty due to availability of material from a common, key, and overburdened manufacturing facility. If this facility runs into production difficulties, several projects will be affected, resulting in consequences across the portfolio. By taking a thorough and thoughtful approach to risk characterization at the project level, the portfolio manager will be able to identify mitigation plans whose implementation has the broadest impact across the portfolio.

A “top-down” approach to portfolio risk can provide a complimentary tool to the “bottom-up” approach. In this process, the portfolio is examined from a strategic perspective to identify patterns or trends in its composition. Consider the example of a pharmaceutical R&D organization. What fraction of the portfolio, and what fraction of the R&D budget, is devoted to projects that are targeting a particular disease state? Suppose that an important regulatory agency issues new guidelines for clinical drug development in this disease state. These new regulations may stipulate that clinical trials in this area must now provide patient exposure data for longer periods of time to better understand long-term safety of drug candidates. As a consequence, both expenses and timelines for projects in this area will be increased. An R&D portfolio that is heavily invested in this disease state is at higher risk for this type of change.

Note that the “top-down” approach has the ability to pick up risk elements that may have been overlooked by some of the project teams. Together, these two approaches both enable and allow for a comprehensive view of portfolio-level risk. While delving deeper into the mechanics and theory of portfolio management is beyond the scope of this work, we recommend Matheson [22] and Cooper *et al.* [23] as excellent departure points for further exploration into this rich area of study.

CONCLUSIONS

Risk management constitutes an important set of activities for managers at all levels in an R&D organization. To make these activities worthwhile, managers must first come to grips with the ambiguity of the term *risk* and recognize that it can apply to one of several uncertainties related to a project's development and commercialization. Thoughtful and careful identification and characterization of these risks can lead to greater insight in the appropriate development of risk mitigation plans at both the project and portfolio level. Well-articulated risk management plans can then effectively inform an organization's risk communication plan to guide internal and external messages to the project participants, portfolio managers, and outside stakeholders.

RANDOM SEARCH ALGORITHMS

ZELDA B. ZABINSKY

Department of Industrial and Systems
Engineering, University of Washington,
Seattle, Washington

A random search algorithm refers to an algorithm that incorporates some kind of randomness or probability (typically in the form of a pseudorandom number generator) in its methodology. The random element may be introduced through sampling specifications of the algorithm, or through noise in the function observation. The random sampling method in the algorithm may include a random search direction and a random step size, as is common for continuous problems, or a random permutation of variables, such as cities in the traveling salesperson problem (TSP). Randomness may also be included when the objective function is only available through noisy measurements. In the literature, a random search algorithm may be called a *Monte Carlo method* or a *stochastic algorithm*. The term *metaheuristic* is also commonly associated with random search algorithms. Simulated annealing, tabu search, genetic algorithms (GAs), evolutionary programming, particle swarm optimization (PSO), ant colony optimization, cross-entropy, stochastic approximation, multistart, clustering algorithms, and other random search methods are being widely applied to continuous and discrete global optimization problems [1–8]. Random search algorithms are useful for ill-structured global optimization problems, where the objective function may be nonconvex, multimodal, nondifferentiable, and possibly discontinuous over a continuous, discrete, or mixed continuous–discrete domain. Random search algorithms have been applied to many ill-structured optimization problems that arise in complex systems including engineering design problems, scheduling and sequencing problems, and other applications in biological and economic systems.

The problem of designing algorithms that obtain global optimal solutions is very difficult when there is no overriding structure that indicates whether a local solution is indeed a global solution. In contrast to deterministic methods such as branch and bound, interval analysis, and tunneling methods [4,9,10], which typically guarantee asymptotic convergence to the optimum, random search algorithms ensure convergence in probability. The trade-off is in terms of computational effort. Random search algorithms are popular because they can provide a relatively good solution quickly and easily.

Random search methods have been shown to have a potential to solve large-scale problems efficiently in a way that is not possible for deterministic algorithms. Whereas it is known that a deterministic method for global optimization is NP-hard [11], there is evidence that a stochastic algorithm can be executed in polynomial time, on the average. For instance, Dyer and Frieze [12,13] showed that estimating the volume of a convex body takes an exponential number of function evaluations for *any* deterministic algorithm, but if one is willing to accept a weaker claim of being correct with a high probability, then a stochastic algorithm can provide such an estimate in polynomial time.

Another advantage of random search methods is that they are relatively easy to implement on complex problems with black-box function evaluations. Because the methods typically only rely on function evaluations, rather than gradient and Hessian information, they can be coded quickly, and applied to a broad class of global optimization problems. A disadvantage of these methods is that they are currently customized to each specific problem largely through trial and error. A common experience is that random search algorithms perform well and are “robust” in the sense that they give useful information quickly for ill-structured global optimization problems.

The term *stochastic optimization*, as used in Ref. 6, includes problems with noisy

measurements in the objective functions in addition to algorithms that incorporate a random element. Here we focus on algorithms that incorporate some form of randomness in their definition, even though they are applied to deterministic or noisy functions. Whether the function evaluations are deterministic or noisy, the function values are typically evaluated through a complicated computer program and/or Monte Carlo simulation and have no known structure. In contrast, well-structured noisy problems such as stochastic linear programs with recourse have specialized methods.

Different types of categorizations have been suggested for random search algorithms. Schoen [14] provides a classification of a two-phase method, where one phase is a global search phase and the other is a local search phase. The global phase is also referred to as an *exploration phase* aimed at exploring the entire feasible region, while the local phase is referred to as an *exploitation phase* aimed at exploiting local information. One example of a two-phase method is multistart, where the global phase is typically a uniform random search and the local phase is a deterministic gradient search. Another example is GAs, where the global or exploration phase is associated with the mutation operation and the local or exploitation phase is the crossover operation.

Zlochin [15] categorizes random search algorithms as instance-based or model-based, where instance-based methods generate new candidate points based on the current point or population of points, and model-based methods rely on an explicit sampling distribution and update parameters of the probability distribution. Examples of instance-based algorithms include simulated annealing, GAs, and tabu search, whereas examples of model-based algorithms include ant colony optimization, stochastic gradient search, and the cross-entropy method.

To understand the differences between random search algorithms, we concentrate on the procedures of generating new candidate points, and updating the collection of points maintained. The next section describes generating and updating procedures for several random search algorithms. Even though

instance-based methods may use heuristics to generate and update points, they do implicitly induce a sampling distribution. Abstracting the random search algorithms by a sequence of sampling distributions (whether implicit or explicit) provides a means to understand the performance of the algorithms. In the section titled, “Performance of Pure Random Search, Pure Adaptive Search, and Annealing Adaptive Search,” we analyze the performance of pure random search (PRS), pure adaptive search (PAS) and annealing adaptive search (AAS) by investigating their sampling distributions. We discuss model-based methods in the context of their explicit sampling distribution and a metacontrol framework in the section titled, “Cross-entropy and other Model-based Methods,” where algorithm parameters affecting the sampling distributions are adapted based on observed function values. We hope this overview serves to assist researchers in using random search algorithms and developing better methods in the future.

GENERIC RANDOM SEARCH AND SPECIFIC ALGORITHMS

The general global optimization problem (P) used here is defined as,

$$\min_{x \in S} f(x),$$

where x is a vector of n decision variables, S is an n -dimensional feasible region and assumed to be nonempty, and f is a real-valued function defined over S . The goal is to find a value for x contained in S that minimizes f . The objective function may be an oracle, or black-box function, in the sense that an explicit mathematical expression is not required but a numerical value for f must be returned for an input value of x . The feasible set S may be represented by a system of nonlinear equations, such as $g_j(x) \leq 0$ for $j = 1, \dots, m$, or by a membership function that simply returns whether or not a given x is in S . Notice that the feasible region may include both continuous and discrete variables. Denote the global optimal solution to

(P) by (x_*, y_*) where

$$x_* = \arg \min_{x \in S} f(x) \text{ and } y_* = f(x_*) = \min_{x \in S} f(x).$$

Random search algorithms are also frequently applied to stochastic optimization problems (also known as *simulation-optimization*) where the objective function and constraints involve randomness in the form of noisy measurements. In this case, the objective function is often the expectation of a function of a random variable, such as,

$$f(x) = E[F(x, Y_x)],$$

where F is a real-valued function of x and a random variable Y_x that may depend on $x \in S$. We assume the expectation exists and is finite, however, in practice the probability distribution is not known, and only realizations of F for specific values of x and y_x can be obtained.

In order to ensure a global optimum exists, we need to assume some regularity conditions. If (P) is a continuous problem and the feasible set S is nonempty and compact, then the Weierstrass theorem from classical analysis guarantees the existence of a global solution [16]. If (P) is a discrete problem and the feasible set S is nonempty and finite, a global solution exists. The existence of a global optimum can be guaranteed under slightly more general conditions. Note that the existence of a *unique* minimum at x_* is not required. If there are multiple optimal minima, let x_* be an arbitrary fixed global minimum.

In order to describe random search algorithms on continuous and/or discrete domains, it is necessary to assume some concept of neighborhood. In Euclidean space (real or integer valued variables), the notion of neighborhood is typically defined by a ball of radius $\delta, \delta > 0$, of points that are within a (Euclidean) distance δ of a point $x \in S$. However, the distance between points could be associated with the algorithm, rather than the problem domain. For example, the TSP in combinatorial optimization has several possible neighborhood structures (e.g., one-city swap, two-city swap) that are integrally associated with the search algorithm. Even for problems

with a continuous domain, the neighborhood associated with an algorithm with a short step size would differ from the neighborhood of an algorithm with a large step size. Thus the term *local search* must be tempered with the concept of the algorithm's neighborhood.

We describe a generic random search algorithm by a sequence of iterates X_k on iteration $k = 0, 1, \dots$ which may depend on previous points and algorithmic parameters. The current iterate X_k may represent a single point, or a collection of points, to include population-based algorithms. The iterates are also capitalized to denote that they are random variables, reflecting the probabilistic nature of the random search algorithm.

Generic Random Search Algorithm

Step 0. Initialize algorithm parameters Θ_0 , initial points $X_0 \subset S$ and iteration index $k = 0$.

Step 1. Generate a collection of candidate points $V_{k+1} \subset S$ according to a specific *generator* and associated *sampling distribution*.

Step 2. Update X_{k+1} based on the candidate points V_{k+1} , previous iterates and algorithmic parameters. Also update algorithm parameters Θ_{k+1} .

Step 3. If a stopping criterion is met, stop. Otherwise increment k and return to Step 1.

This generic random search algorithm depends on two basic procedures, the generator in Step 1 that produces candidate points, and the update procedure in Step 2. We first discuss some examples for the generator procedure.

Single-Point Generators. Many random search algorithms maintain and generate a single point at each iteration. For these single-point generators, the candidate point V_{k+1} is generated based on a combination of the current point and previous points. A common method to generate a candidate point is to take a step size in a vector direction, called a *direction-step paradigm* in Ref. 5, or also known as *step size algorithms*.

Step 1 of a step size algorithm can be expressed by

$$V_{k+1} = X_k + S_k D_k,$$

where the candidate point is generated by taking a step from the current point X_k of length S_k in a specified direction D_k on iteration k . In continuous problems, the direction of movement D_k may be motivated by gradient information, and if the objective function is noisy, then the probability distribution of D_k is related to the estimate of the gradient. The step length may be the result of a line search or an independent random step length. Quasi-Newton methods take advantage of an approximation of the Hessian to provide a search direction. In the basic method of stochastic approximation, also referred to as the *Robbins–Monro algorithm*, the direction of movement is a stochastic approximation to the gradient, and the step length is referred to as the *gain* [6]. If the direction is closely related to the gradient, as in stochastic gradient search, then local convergence may be proven under certain conditions, however, other variations must be introduced to escape local minima and find the global minimum.

As an alternative, a direction D_k that does not use any local information and is generated according to a uniform distribution on a hypersphere has been investigated. A collection of step size algorithms, including Refs 17–23, obtain a direction vector by sampling from a uniform distribution on a unit hypersphere. The method of choosing the step size may also be randomly generated, and may shrink or expand depending on the success of previously sampled points. It is interesting that several of these step size random search algorithms report experiencing computation that is linear in dimension.

The algorithm improving hit-and-run (IHR) also generates a direction uniformly on a hypersphere, and generates a step size according to a uniform distribution on the feasible portion of the line segment in direction D_k [23]. This simple generator is motivated by convergence properties of a Markov chain Monte Carlo sampler called *hit-and-run* to a target distribution [24–27].

The hit-and-run generator coupled with an update procedure has been used in several simulated annealing algorithms [28–30]. The update procedure in IHR is simply to only accept improving points. Even though this is a straightforward random search algorithm, its expected performance on a class of spherical programs is polynomial $O(n^{5/2})$ in dimension [23].

Examples of generators on discrete domains include nearest neighbor or local search, ball walk, k -city swap for TSP, and more recently, very large-scale neighborhood search (VLSN) [31]. Classical Markov chains such as the nearest neighbor random walk or the coordinate direction random walk can get trapped in isolated regions of the domain. A variation of hit-and-run has been proven to converge to an arbitrary target distribution over an arbitrary subset S of an integer hyperrectangle [32]. An extension of hit-and-run to mixed continuous/integer domains using a pattern generator has recently been embedded in IHR for global optimization [33]. The generator in tabu search is known for its restriction on neighborhoods—it uses a local neighborhood but prevents points from being generated that have been recently visited [3,34]. In simulated annealing, the specific method of generating a candidate point based on the neighborhood structure can be described as a Markov chain. As such, we view it as inducing an implicit sampling distribution.

Multiple-Point Generators. Population-based random search algorithms use a collection of current points to generate another collection of candidate points. Many of these algorithms are motivated by biological processes, and include GAs, evolutionary programming, PSO, and ant colony optimization. The concept behind GAs and evolutionary programming [35–37] is to produce “off-spring” of the current population with parameters related to reproduction (e.g., genetic crossover). PSO [38,39] is based on the social behavior of birds and schools of fish, communicating to find food. Once an individual in the group finds a food source (associated with an objective function value),

it informs the others. While initially the individuals of the group behave independently, they eventually communicate and move collectively toward one of the found sources of food. The individuals, or particles in the swarm, are typically modeled by position and velocity, which are updated based on the success of the other particles in the group. Ant colony optimization [40] is also considered a swarm intelligence, where the population of ants are moving individually, but communicate through a pheromone that provides feedback as to successful locations.

Another multiple-point generator that uses a population of points is differential evolution [41] which uses a weighted difference between two population vectors to generate a third vector. It is similar to the particle swarm generator because no explicit probability distribution is used, but an implicit empirical distribution is created through the interaction of the points. The generator procedure is just telling part of the story. The update procedure also influences the resulting probability distribution underlying the random search method.

Update Procedure. After a candidate point is generated, Step 2 of the generic random search algorithm specifies a procedure to update the current point and algorithm parameters. Algorithms that are strictly improving have a simple procedure, update the current point only if the candidate point is improving,

$$X_{k+1} = \begin{cases} V_{k+1}, & \text{if } f(V_{k+1}) < f(X_k), \\ X_k, & \text{otherwise.} \end{cases}$$

This type of improving algorithm may get trapped in a local optimum if the neighborhood, or procedure for generating candidate points is too restricted. One remedy is to sample a large neighborhood, as in VLSN or to draw from the entire feasible set. Although IHR has a simple acceptance procedure, it converges in probability to the global optimum because its generator has a positive probability of sampling anywhere in the bounded feasible region. Another approach is to accept nonimproving points, as in simulated annealing.

In simulated annealing [42–44], the update procedure is the Metropolis criterion, and the candidate point is accepted with a probability that reflects a Boltzmann distribution,

$$X_{k+1} = \begin{cases} V_{k+1}, & \text{with probability} \\ & \min \left\{ 1, \exp \left(\frac{f(X_k) - f(V_{k+1})}{T_k} \right) \right\}, \\ X_k, & \text{otherwise.} \end{cases}$$

In contrast to algorithms with strict improvement, simulated annealing allows nonimproving points to be accepted, which provides a means to escape a local optimum. With the Metropolis acceptance/rejection criterion, improving points are accepted with probability one, and the probability of accepting a worse point decreases as the temperature parameter cools, that is, decreases to zero. The update of the temperature parameter, called the *cooling schedule*, has been studied in the literature [28,45–49]. Typically the temperature parameter decreases monotonically, however, recent research on dynamically heating and cooling the temperature in an interacting particle algorithm [50] is discussed later in this article.

The update procedure for GAs and evolutionary programming is called the *selection criterion*. A straightforward scheme is to rank the population of points based on objective function value (also referred to as the *fitness function*), and select the top percentile of points to use in reproduction and recombination. However experience has shown that some diversity should be maintained to prevent premature convergence to a local optimum. The elitist strategy subdivides the population into three categories: the elite (best) solutions, the immigrant solutions (added to maintain diversity), and the crossover solutions [5]. This ensures that the best solutions are always carried to the next generation of points. The most effective proportion of elite, immigrant, and crossover solutions requires computational experimentation. An effective population size for a particular problem also requires experimentation. Researchers have used Markov chain analysis to analyze the behavior, such as the expected waiting time, of genetic algorithms [51,52].

Multistart and Clustering Algorithms. Algorithms may modify their generating and updating procedures per iteration. Consider multistart; on one iteration a candidate point is generated according to a global sampling distribution (e.g., a uniform distribution) on S , but on the next iteration a local search sampling distribution (e.g., a stochastic gradient search) is used. The update procedure is viewed as setting an indicating parameter to determine whether a global or local sample is generated for the next candidate point. These methods are often called *two-phase methods* [14]. Different combinations of sampling distributions can be created, such as generating uniformly distributed points in the global phase that initiate simulated annealing in the local phase, or use simulated annealing in the global search phase to initiate stochastic gradient search or nearest neighbor local searches.

An inefficiency in multistart is that the same local optimum may be repeatedly discovered from many different starting points. This has motivated clustering methods where clusters are formed (often grown around a seed point) to predict whether a starting point is likely to lead to a new local optimum or one that has already been discovered. Then local searches are only initiated at promising candidate points [7,14]. The update procedure may involve a sophisticated statistical analysis to decide whether to initiate a local search, as well as when to terminate a local search and generate more global candidate points. A related idea has led to linkage methods, which “link” points in the sample and essentially view clusters as trees, instead of spherical or ellipsoidal clusters. The well-known linkage method called *multilevel single linkage* [53,54] and several variants including random linkage [55] are summarized in Ref. 14.

More recently, a multistart heuristic for OptQuest/Nonlinear Programming, has been designed to operate on mixed integer nonlinear problems where the functions are differentiable with respect to the continuous variables [56]. They use scatter search (related to evolutionary programming) in the global search phase, and use filtering instead of clustering to decide when to initiate a

local search. The nested partitioning method [57] is based on a partitioning of the feasible region that can be viewed as the global phase, coupled with local random search within the subregions.

Convergence in Probability. Solis and Wets [22] provide a convergence proof, in probability, to the global minimum for general step size algorithms with conditions on the method of generating the step length and direction. Essentially, as long as the generator does not consistently ignore any region, then the algorithm will converge with probability one. Another convergence proof due to Bélisle [24] says that, even if the generator of an algorithm cannot reach any point in the domain in one iteration, if there is a means such as an acceptance probability to allow the algorithm to reach any point in a finite number of iterations, then the algorithm still converges with probability one to the global optimum. Stephens and Baritompä [58] go on to prove that an algorithm must either sample the entire region or use global information regarding the structure of the problem to provide convergence results. Examples of global information are bounds on the function, a Lipschitz constant, information on the level sets, number of local optima, functional form, and the global optimum itself. They conclude that using “global optimization heuristics is often far more practical than running general algorithms until the mathematically proven stopping criteria are satisfied” (58, p. 587).

The generating and updating procedures for random search algorithms can be viewed as Markov chain Monte Carlo samplers, and then the algorithms can be interpreted as implicitly or explicitly sampling from a sequence of distributions. Markov chain theory has been applied to the analysis of several versions of these algorithms, including simulated annealing and GAs, to prove convergence.

Several convergence results are also available for random search algorithms applied to noisy objective functions. Convergence results for simulated annealing applied to discrete problems with noisy function evaluations are reviewed in Ref. 59, and the authors prove that simulated annealing

with constant temperature converges almost surely to the set of global optimizers under mild assumptions on the Markov chain associated with the candidate point generator and with strongly consistent estimates of the objective function. Spall (6, Section 8.6) summarizes convergence results on continuous problems with noisy objective functions relating simulated annealing to stochastic approximation methods. GAs have also been applied to noisy functions but Spall remarks that “there appears to be relatively little formal analysis of GAs in the presence of noise” (6, p. 248). The nested partitioning method, introduced in Ref. 57 for objective functions that can be evaluated deterministically, was adapted for objective functions with noisy evaluations in Ref. 60 and shown to converge with probability one on discrete domains under mild assumptions. Cross-entropy and model reference adaptive search (MRAS) have also been applied to both deterministic and noisy objective functions, and are discussed in the section titled “Cross-Entropy and other Model-Based Methods”.

We next analyze the performance of three algorithms with explicit sampling distributions: PRS, PAS, and AAS, to gain insight into the distributions we could approximate with generating and updating procedures.

PERFORMANCE OF PURE RANDOM SEARCH, PURE ADAPTIVE SEARCH, AND ANNEALING ADAPTIVE SEARCH

The simplest and most obvious random search method is a “blind search” as discussed in Ref. 6, or called *pure random search* in Ref. 8. PRS was first defined in 1958 by Brooks [61] for problems with continuous variables, and discussed later in Refs 62 and 63. PRS is also easily defined for problems with discrete variables, as in Refs 6 and 8. PRS generates samples repeatedly from the feasible region S , typically according to a uniform sampling distribution. In the context of the generic random search algorithm, each candidate point is generated independently from a uniform distribution (continuous or discrete, as appropriate) on

S , and X_{k+1} is updated only if the candidate point is improving. It can be shown that PRS converges to within an ϵ distance of the global optimum with probability one [8,22]. PRS is often the global phase in multistart and clustering algorithms.

Even though PRS converges almost surely [6], it will take a long time. In order to describe the performance of PRS, we use $E[N(y_* + \epsilon)]$, the expected number of iterations until a point within ϵ distance of the global minimum is first sampled, as a measure of computational complexity. For PRS, an iteration generates one point uniformly (continuous or discrete, as appropriate) on S and performs exactly one function evaluation, so this captures the majority of the computational effort. The random variable $N(y)$, the number of iterations until a point is first sampled with an objective function value of y or less, has a geometric distribution [64], where the probability of a “success” is $p(y)$, the probability of generating a point in the level set $S(y)$, where $S(y) = \{x \in S : f(x) \leq y\}$. Then, the expected number of iterations until a point is first sampled within ϵ distance of the optimum is

$$E[N(y_* + \epsilon)] = 1/p(y_* + \epsilon).$$

This relationship supports the natural intuition that, as the target region close to the global optimum gets small (i.e., $p(y_* + \epsilon)$ gets small), the expected number of iterations gets large (inversely proportional). For a discrete problem, ϵ may equal zero, whereas for a continuous problem, ϵ is taken as a small positive value. The probability of failure to achieve $y_* + \epsilon$ after k iterations is $(1 - p(y_* + \epsilon))^k$. The variance of the number of iterations until a point first lands in $S(y)$ is

$$\text{Var}(N(y)) = \frac{1 - p(y)}{p(y)^2}.$$

This supports numerical observations that PRS (and other random search methods) experiences large variation; as the probability $p(y)$ decreases, the variance of $N(y)$ increases.

To gain insight into the performance of PRS, consider the TSP with N cities and

subsequently $(N - 1)!$ possible points in the domain. If there is a unique minimum, then $p(y_*) = 1/(N - 1)!$ and the expected number of PRS iterations to first sample the minimum is $(N - 1)!$, which explodes in N .

To illustrate the performance of PRS on a continuous domain problem, consider a global optimization problem where the domain S is an n -dimensional ball of radius 1, and the area within ϵ distance of the global optimum is a ball of radius ϵ , for $0 < \epsilon \leq 1$. Using a uniform sampling distribution on this problem, $p(y_* + \epsilon) = \epsilon^n$ for $0 < \epsilon \leq 1$ and the expected number of iterations until a sample point falls within the ϵ -ball is $(1/\epsilon)^n$, an exponential function of dimension.

To expand this example, it is shown in Ref. 8 that the expected number of PRS iterations on a global optimization problem where the objective function satisfies a Lipschitz condition with constant K is also exponential in the dimension of the problem,

$$E[N(y_* + \epsilon)] = (K/\epsilon)^n.$$

All random search algorithms are meant to improve upon PRS. However, the “No Free Lunch” theorems in Wolpert and Macready [65] show that, in essence, no single algorithm can improve on any other when averaged across all possible problems. As a consequence of these theorems, in order to improve upon PRS, we must either restrict the class of problems, have some prior information, or adapt the algorithm as properties of a specific problem are observed.

In contrast to PRS, where each sample is independent and identically distributed, we next consider PAS, where each sample depends on the one immediately before it. PAS was introduced in Ref. 66 for convex programs and later analyzed for global optimization problems with Lipschitz continuous functions in Ref. 67 and for finite domains in Ref. 68. It was generalized as hesitant adaptive search in Refs 69 and 70. PAS, by definition, generates a candidate point uniformly in the subset of the domain that is strictly improving, $V_{k+1} \in S(f(X_k)) = \{x : x \in S \text{ and } f(x) < f(X_k)\}$. It is an idealized algorithm to show potential performance for a random search

algorithm. Whereas, sampling from a uniform distribution in PRS over S is typically very easy (e.g., if S is a hyperrectangle), sampling from a uniform distribution in PAS over $S(f(X_k))$ is very difficult in general. However, the analysis shows the value of being able to find points in the improving level set; the number of iterations of PAS is an exponential improvement over the number of iterations in PRS (8, Theorem 2.2). Additionally, for Lipschitz continuous objective functions, the expected number of iterations of PAS is *linear* in dimension (8, Theorem 2.9), with an analogous result for finite domains (8, Corollary 2.9). The linearity result for PAS implies that adapting the search to sample improving points is very powerful.

The idealistic linear property of PAS has inspired the design of several algorithms with the goal of approximating PAS, including IHR [23] which uses hit-and-run as a Markov chain Monte Carlo sampler embedded in an optimization context, and Grover Adaptive Search [71] which uses quantum computing for optimization.

We now describe one more idealistic algorithm, AAS, which is a way to abstract simulated annealing. AAS differs from PAS in that the candidate points are generated from the entire feasible set S according to a Boltzmann distribution parameterized by temperature, whereas the sampling distribution in PAS only has positive support on nested level sets of S . The name AAS [72] is used because the algorithm assumes that points can be generated from exact Boltzmann distributions, which is a model of simulated annealing. The purpose of the AAS analysis is to gain understanding of simulated annealing and other stochastic algorithms.

The record values (best values observed) of AAS, first analyzed in Ref. 29, stochastically dominate those of PAS and hence inherit the ideal linear complexity of PAS. The number of sample points (including nonimproving points) of AAS is also shown to be linear on average under certain conditions on the cooling schedule for the temperature parameter. The analysis motivated a cooling schedule for simulated annealing which maintains a linear complexity in expected

number of sample points on a class of (Lipschitz) objective functions over both continuous and discrete domains [49].

CROSS-ENTROPY AND OTHER MODEL-BASED METHODS

In keeping with our generic random search algorithm, we now relate model-based methods to the generating and updating procedures. We view instance-based methods as emphasizing generating new points and subsequently updating them using algorithm parameters Θ_k , but now model-based methods change the emphasis to updating the algorithm parameters Θ_k and subsequently using them to generate new points. In this section, we discuss three methods that adapt the algorithm parameters using a model of the sampling distribution: cross-entropy, MRAS, and metacontrol.

To contrast instance-based and model-based methods, we compare them to an idealized algorithm, such as PAS or AAS, where we want to sample points according to a sequence of probability density functions $h_k(x)$. In PAS, the sampling distribution $h_k(x)$ is uniform on the level set associated with the best objective function value on the k th iteration. In AAS, the sampling distribution $h_k(x)$ is Boltzmann with a temperature parameter associated with the k th iteration. In both PAS and AAS, if we could sample directly from $h_k(x)$, the algorithm would have excellent performance. However, sampling directly from $h_k(x)$ is difficult, so we have to use an approximation. Instance-based methods can be interpreted as a Markov chain sampling approach to approximate $h_k(x)$. For example, IHR can be interpreted as a Markov chain sampling approach to approximate a series of PAS uniform distributions on level sets, and simulated annealing can be interpreted as a Markov chain sampling approach to approximate a series of AAS Boltzmann distributions. Model-based methods approximate a sequence of distributions $h_k(x)$ with a family of distributions that can be sampled from directly. The parameters of the distribution are adapted based on observed values.

Model-based methods, as discussed in Ref. 15, include ant colony optimization, stochastic gradient search, cross-entropy, and estimation of distribution methods. The MRAS algorithm introduced in Ref. 75 is also considered a model-based method.

Cross-entropy [73,74] and MRAS [75] use the idea of importance sampling, or sequential importance sampling, to approximate a sequence of target distributions $h_k(x)$. The idea is to use a simple parametrized probability density function $g(x, \Theta)$ that is easy to sample from, and update the parameter Θ so that the new samplings are biased toward the global optimum. Choices for $g(x, \Theta)$ typically come from the natural exponential family, which include Gaussian, Poisson, binomial, geometric, and other multivariate forms [73,74,75]. For example, when the Gaussian probability density function is used, then Θ consists of the mean vector and the covariance matrix. We now seek a parameter Θ_{k+1} that provides a good approximation to $h_k(x)$. This leads to the problem of minimizing the Kullback–Leibler divergence between $g(x, \Theta)$ and $h_k(x)$, that is

$$\Theta_{k+1} = \arg \inf_{\Theta} \int_S \ln \left(\frac{h_k(x)}{g(x, \Theta)} \right) h_k(x) dx.$$

The name of the cross-entropy method comes from this idea because the Kullback–Leibler divergence is also referred to as the *cross-entropy* between two probability density functions.

Now a new probability density function $h_{k+1}(x)$ is created by “tilting” $h_k(x)$ to bias it toward the improving regions in S using a performance function $G_y(x)$, as follows

$$h_{k+1}(x) = \frac{G_{y_{k+1}}(x)h_k(x)}{\int_S G_{y_{k+1}}(x)h_k(x) dx}.$$

The performance function $G_y(x)$ is assumed to be positive and relates to the objective function $f(x)$. One alternative for a performance function is $G_{y_{k+1}}(x) = \exp(f(x)) I_{S(y_{k+1})}(x)$ where

$$I_{S(y_{k+1})}(x) = \begin{cases} 1, & \text{if } x \in S(y_{k+1}), \\ 0, & \text{otherwise,} \end{cases}$$

is the indicator of the level set $S(y_{k+1})$. A sample of candidate points drawn from the sampling distribution $g(x, \Theta_{k+1})$ is used to determine a level set threshold y_{k+1} . In Ref. 75, y_{k+1} is estimated as a specified quantile of $f(x)$ with respect to $h_k(x)$.

Global convergence properties of these model-based methods appear in Refs 15, 73, 75 for both continuous and discrete domains. Cross-entropy and MRAS have also been applied successfully to noisy objective functions [73,76]. Convergence results for cross-entropy applied to the noisy buffer allocation problem and noisy TSP are summarized in Ref. 73, Chapter 6. Convergence properties for a version of MRAS for noisy objective functions on continuous and discrete domains are given in Ref. 76.

To complete this article, we mention recent work on a metacontrol methodology for adapting algorithm parameters based on observed values. Metacontrol of a deterministic optimization algorithm was introduced in Ref. 77, and extended to a random search algorithm in Ref. 50, where the temperature parameter is dynamically controlled in the interacting particle algorithm.

The interacting particle algorithm in Refs 50 and 78 is based on Feynman–Kac systems in statistical physics [79,80] and combines the ideas of simulated annealing with population-based algorithms. As such, it has a temperature parameter that influences the sampling distribution through acceptance/rejection. Instead of choosing a cooling schedule a priori, the metacontrol methodology dynamically determines the temperature parameter by adapting it based on observed sample points. An optimal control problem that controls the evolution of the probability density function of the particles with the temperature parameter is defined to make the algorithm’s search process satisfy specified performance criteria. The criteria in Ref. 50 include the expected objective function value of the particles, the spread of the particles, and the algorithm running time. Numerical results indicate improved performance by allowing heating and cooling of the temperature parameter through the metacontrol methodology [50]. The metacontrol methodology shares a

common goal with cross-entropy and MRAS: to provide a means to dynamically adapt algorithm parameters based on observed values in a closed-loop with feedback.

In this article, a generic random search algorithm is used to provide a common language to describe a variety of random search algorithms. Theoretical properties of convergence and performance are discussed to provide insight into the behavior of random search algorithms. Several model-based methods are reviewed with different approaches to adapt algorithm parameters. This serves as a starting point for researchers and practitioners interested in developing and applying random search algorithms for solving ill-structured global optimization problems.

RANDOM VARIATE GENERATION

LAWRENCE M. LEEMIS
Department of Mathematics,
The College of William &
Mary, Williamsburg
Virginia

This article concerns algorithms for generating random variates that are typically used in Monte Carlo simulation (where the passage of time plays no role) or discrete-event simulation (where the passage of time plays a significant role). There is a subtle but important distinction between a random variable and a random variate. A *random variable* is a rule that assigns a real number to an outcome of an experiment. A *random variate* is a realization, or instantiation of a random variable, which is typically generated by a computer. Devroye [1] and Hörmann *et al.* [2] provide both an introductory and an encyclopedic treatment of variate generation.

The four functions—the cumulative distribution function, the probability density function, the hazard function, and the cumulative hazard function (chf)—describe the distribution of a random variable X .

The cumulative distribution function (cdf) of a random variable X ,

$$F(x) = P(X \leq x),$$

is a nondecreasing function of x satisfying $\lim_{x \rightarrow -\infty} F(x) = 0$ and $\lim_{x \rightarrow \infty} F(x) = 1$. When the cdf is differentiable,

$$f(x) = F'(x)$$

is the associated probability density function (pdf). For any interval (a, b) , where $a < b$,

$$P(a < X < b) = \int_a^b f(x) dx.$$

For discrete distributions, $F(x)$ is a step function and the mass values of $f(x)$ associated with the support values are equal to the heights of the steps in $F(x)$.

The hazard function, also known as the *rate function*, *failure rate*, and *force of mortality*, can be defined by

$$h(x) = \frac{f(x)}{1 - F(x)}.$$

The hazard function is popular in reliability and survival analysis because it has the intuitive interpretation as the amount of *risk* associated with an item that has survived to time x . The hazard function is mathematically equivalent to the intensity function for a nonhomogeneous Poisson process, and the failure time corresponds to the first event time in the process. Competing risk models are naturally formulated in terms of $h(x)$, as shown subsequently. The cumulative hazard function can be defined by

$$H(x) = \int_0^x h(y) dy.$$

We assume that there is a reliable source of pseudorandom numbers available, and we use U , with or without subscripts, to denote one instance of such a $U(0, 1)$ random variable. Any of the standard discrete-event simulation textbooks [3,4] contain a discussion of random number generation techniques. The purpose of this article is to present an overview of several random variate generation techniques that convert random numbers to random variates. The algorithms are broken into density-based algorithms and hazard-based algorithms, and there are analogies between the two sets of algorithms. A group of algorithms known as *special properties* (e.g., the sum of independent and identically distributed exponential random variables has the Erlang distribution) is neither density based nor hazard based.

There are a number of properties of variate generation algorithms that are important in the evaluation of the algorithms presented here. These include synchronization (one random number produces one random variate), monotonicity (a monotone relationship

between the random numbers and the associated random variates), robustness with respect to all values of parameters, number of lines of code, expected marginal time to generate a variate, setup time, susceptibility to computer round-off, memory requirements, portability, and so on. The choice between the various algorithms presented here must be made based on these criteria. Many of these properties are necessary for implementing “variance reduction techniques” [3].

DENSITY-BASED VARIATE GENERATION METHODS

There are three density-based algorithms for generating random variates: (i) the inverse-cdf technique; (ii) composition, which assumes that the pdf can be written as a convex combination; and (iii) acceptance–rejection, a majorization technique. These three algorithms are introduced in the sections that follow.

Inverse-cdf Technique

The inverse-cdf technique, often called *inversion*, is the algorithm of choice for generating random variate X . It is typically the fastest of the algorithms in terms of marginal execution time, produces a random variate from a single random number, and is monotone. The inverse-cdf technique is based on the probability integral transformation, which states that $F_X(X) \sim U(0, 1)$, where $F_X(x)$ is the cdf of the random variable X . This results in the following algorithm for generating a random variable X .

```
generate  $U \sim U(0, 1)$ 
 $X \leftarrow F^{-1}(U)$ 
return  $X$ 
```

The inverse-cdf technique works well on distributions that have a closed-form expression for $F^{-1}(u)$, for example, the exponential, Weibull, and log logistic distributions. Distributions that lack a closed-form expression for $F^{-1}(u)$, for example, the gamma and beta distributions, can still use the technique by

numerically integrating the pdf, although this tends to be slow. This difficulty leads to the development of other techniques for generating random variates.

Example. For an exponential random variable X with rate $\lambda > 0$, the cdf is given by

$$F(x) = 1 - e^{-\lambda x} \quad x > 0.$$

Inverting this expression yields the random variate generation expression

$$X \leftarrow -\frac{1}{\lambda} \log(1 - U).$$

Although the sense of the monotonicity is reversed, $1 - U$ can be replaced by U to speed up the algorithm by saving a subtraction.

In the previous example, the inverse cdf $F^{-1}(u)$ could be expressed in closed form. For discrete random variables and mixed random variables, however, a true inverse cdf $F^{-1}(u)$ does not exist in the mathematical sense. Devroye [1] gives a careful definition of $F^{-1}(u)$ that allows the inverse-cdf technique to be applied to discrete- and mixed-random variables, as illustrated next.

Example. For a Bernoulli random variable X with parameter $0 < p < 1$, the pdf is given by

$$f(x) = p^x(1 - p)^{1-x} \quad x = 0, 1.$$

A variate generation algorithm for generating a random Bernoulli variate is

```
generate  $U \sim U(0, 1)$ 
if  $X < 1 - p$ 
    return 0
else
    return 1
```

Here, and throughout this article, indentation is used in the algorithms to indicate nesting.

Composition

When the cdf of the random variable X can be written as the convex combination of n cdfs, that is,

$$F_X(x) = \sum_{i=1}^n p_i F_i(x),$$

where $\sum_{i=1}^n p_i = 1$ and $p_i > 0$ for $i = 1, 2, \dots, n$, then the composition algorithm can be used to generate a random variate X . Distributions that can be written in this form are also known as *finite mixture* distributions and there is a significant literature in this area [5,6]. The algorithm generates a random component distribution index I , then generates a variate from the chosen distribution using the inverse-cdf (or any other) technique.

```
generate  $I$  with probability  $p_i$ 
generate  $U \sim U(0, 1)$ 
 $X \leftarrow F_I^{-1}(U)$ 
return  $X$ 
```

This algorithm is not synchronized because two random numbers (one to generate the index I and another to generate X) are required. This difficulty can be overcome with a small alteration of the algorithm that recycles a portion of the random number used to generate the index I . In either case, however, the algorithm is not monotone, which creates difficulties in applying various variance reduction techniques to a simulation.

Acceptance–Rejection

The third and final algorithm is the acceptance–rejection technique, which requires finding a *majorizing function* $f^*(x)$ that satisfies

$$f^*(x) \geq f(x),$$

where $f(x)$ is the pdf of the random variable X . To improve execution time, it is best to find a majorizing function with minimum area. A scaled majorizing function $g(x)$ is

$$g(x) = \frac{f^*(x)}{\int_{-\infty}^{\infty} f^*(y) dy},$$

which is a legitimate pdf with associated cdf $G(x)$. The acceptance–rejection algorithm proceeds as described below.

```
repeat
  generate  $U \sim U(0, 1)$ 
   $X \leftarrow G^{-1}(U)$ 
  generate  $S \sim U(0, f^*(X))$ 
until  $(S \leq f(X))$ 
return  $X$ 
```

The acceptance–rejection algorithm uses a geometrically distributed number of $U(0,1)$'s to generate the random variate X . For this reason, the acceptance–rejection algorithm is not synchronized. The acceptance–rejection technique can be modified to cut its execution time by reducing the number of times that $f(X)$ needs to be evaluated. One of these techniques, the squeeze method, is illustrated in Schmeiser and Lal [7].

HAZARD-BASED VARIATE GENERATION METHODS

There are three hazard-based algorithms for generating random variates: (i) the inverse cumulative hazard function technique, an inversion technique that parallels the inverse-cdf technique; (ii) competing risks, a linear combination technique that parallels composition; and (iii) thinning, a majorization technique that parallels acceptance–rejection. These three algorithms are introduced in the sections that follow. Random numbers are again denoted by U and the associated random variates are denoted by X , consistent with the notation in the previous section. (Since hazard functions are commonly used in reliability and survival analysis, T , for *time*, is often used instead of X .)

Inverse Cumulative Hazard Function Technique

If X is a random variable with cumulative hazard function H , then $H(X)$ is an exponential random variable with a mean of 1. This

result, which is an extension of the probability integral transformation, is the basis for the inverse-chf technique. Therefore,

```
generate  $U \sim U(0, 1)$ 
 $X \leftarrow H^{-1}(-\log(1 - U))$ 
return  $X$ 
```

generates a single random lifetime X . This algorithm is the easiest to implement when H can be inverted in closed form. This algorithm is monotone and synchronized. Although the sense of the monotonicity is reversed, $1 - U$ can be replaced with U in order to save a subtraction. For identical values of U , the inverse-cdf technique and the inverse-chf technique generate the same random variate X .

Competing Risks

Competing risks [8,9] is a linear combination technique that is analogous to the density-based composition method. The competing risks technique applies when the hazard function can be written as the sum of hazard functions, each corresponding to an independent “cause” of failure

$$h(x) = \sum_{j=1}^k h_j(x),$$

where $h_j(x)$ is the hazard function associated with cause j of failure acting in a population. The minimum of the lifetimes from each of these risks corresponds to the system lifetime. Competing risks is most commonly used to analyze a series system of k independent components, but can also be used in actuarial applications with k independent causes of failure. The algorithm to generate a random variate X is

```
for  $j$  from 1 to  $k$ 
  generate  $X_j \sim h_j(x)$ 
 $X \leftarrow \min\{X_1, X_2, \dots, X_k\}$ 
return  $X$ 
```

The $X_1, X_2, \dots, X_k$ values can be generated by any of the standard random variate generation algorithms.

Thinning

The *thinning* algorithm, which was originally suggested by Lewis and Shedler [10] for generating the event times in a nonhomogeneous Poisson process, can be adapted to produce a single lifetime by returning only the first event time generated. A majorizing hazard function $h^*(x)$ must be found that satisfies $h^*(x) \geq h(x)$ for all values of x in the support of X . The algorithm is

```
 $X \leftarrow 0$ 
repeat
  generate  $Y$  from  $h^*(x)$  given  $Y > X$ 
   $X \leftarrow X + Y$ 
  generate  $S \sim U(0, h^*(X))$ 
until  $S \leq h(X)$ 
return  $X$ 
```

Generating Y in the repeat–until loop can be performed by inversion or any other method. The name *thinning* comes from the fact that X can make several steps, each of length Y , that are thinned out before the repeat–until loop condition is satisfied.

GENERATING STOCHASTIC PROCESSES

Most discrete-event simulation models have stochastic elements that mimic the probabilistic nature of the system under consideration. The focus in this section is on the generation of a sample realization of a small group of stochastic point processes. These models are used by probabilists to model the arrival times of customers to a queue, the arrival times of demands in an inventory system, the failure times of a repairable system, the times of the births of babies, and so on. These stochastic models generalize to model events that occur over time or space. The general question considered here is how to generate a sequence of event times when underlying stochastic process is known. We begin by introducing probabilistic models for sequences of events that occur at points in time. A special case of a point process is a “counting process,” where event occurrences increment a counter.

Counting Processes

A continuous-time, discrete-state stochastic process is often characterized by the *counting function* $\{N(t), t \geq 0\}$ which represents the total number of events that occur by time t [11]. A counting process satisfies the following properties:

1. $N(t) \geq 0$,
2. $N(t)$ is integer-valued,
3. if $s < t$, then $N(s) \leq N(t)$, and
4. for $s < t$, $N(t) - N(s)$ is the number of events in $(s, t]$.

Two important properties associated with some counting processes are *independent increments* and *stationarity*. A counting process has independent increments if the number of events that occur in mutually exclusive time intervals is independent. A counting process is stationary if the distribution of the number of events that occur in any time interval depends only on the length of the interval. Thus, the stationarity property should only apply to counting processes with a constant rate of occurrence of events.

Counting processes can be used in modeling events as diverse as earthquake occurrences [12], storm occurrences in the Arctic Sea [13], customer arrival times to an electronics store [14], and failure times of a repairable system [15].

We establish some additional notation at this point which are used in some results and process generation algorithms that follow. Let $X_1, X_2, \dots$ represent the times between events in a counting process. Let $T_n = X_1 + X_2 + \dots + X_n$ be the time of the n th event. With these basic definitions in place, we now define the Poisson process, which is the most fundamental of the counting processes.

Poisson Processes

A Poisson process is a special type of counting process that is a fundamental base case for defining many other types of counting processes.

Definition [11]. The counting process $\{N(t), t \geq 0\}$ is said to be a *Poisson process* with rate λ , $\lambda > 0$, if

1. $N(0) = 0$,
2. the process has independent increments, and
3. the number of events in any interval of length t is Poisson distributed with mean λt .

The single parameter λ controls the rate at which events occur over time. Since λ is a constant, a Poisson process is often referred to as a *homogeneous* Poisson process. The third condition is equivalent to

$$P(N(t+s) - N(s) = n) = \frac{(\lambda t)^n \exp(-\lambda t)}{n!},$$

$$n = 0, 1, 2, \dots,$$

and the stationarity property follows from it.

Although there are many results that follow from the definition of a Poisson process, three are detailed in this paragraph that have applications in discrete-event simulation. Proofs are given in any introductory stochastic processes' textbook. First, given that n events occur in a given time interval $(s, t]$, the event times have the same distribution as the order statistics associated with n independent observations drawn from a uniform distribution on $(s, t]$; see, for example, Rigdon and Basu [16]. Second, the times between events in a Poisson process are independent and identically distributed exponential random variables with pdf $f(x) = \lambda e^{-\lambda x}$, for $x > 0$. Since the mode of the exponential distribution is 0, a realization of a Poisson process typically exhibits significant clustering of events. Since the sum of n independent and identically distributed exponential(λ) random variables is Erlang(λ, n), T_n has a cdf that can be expressed as a summation:

$$F_{T_n}(t) = 1 - \sum_{k=0}^{n-1} \frac{(\lambda t)^k}{k!} e^{-\lambda t} \quad t > 0.$$

Third, analogous to the central limit theorem, which shows that the sum of arbitrarily distributed random variables is asymptotically normal, the superposition of

renewal processes converges asymptotically to a Poisson process [17, p. 318].

The mathematical tractability associated with the Poisson process makes it a popular model. It is the base case for queueing theory (e.g., the M/M/1 queue as defined in Gross and Harris [18]) and reliability theory (e.g., the models for repairable systems described in Meeker and Escobar [19]). Its rather restrictive assumptions, however, limit its applicability. For this reason, we consider the following variants of the Poisson process that can be useful for modeling more complex failure time processes: the renewal process and the nonhomogeneous Poisson process. These variants are typically formulated by generalizing an assumption or a property of the Poisson process. Details associated with these models can be found, for example, in Resnick [20] or Nelson [21].

Renewal Processes

A renewal process is a generalization of a Poisson process. Recall that in a Poisson process, the inter-event times $X_1, X_2, \dots$ are independent and identically distributed exponential(λ) random variables. In a renewal process, the inter-event times are independent and identically distributed random variables from any distribution with positive support. One useful classification of renewal processes [22] concerns the coefficient of variation σ/μ of the distribution of the times between failures. This classification divides renewal processes into underdispersed and overdispersed processes. A renewal process is *underdispersed* (*overdispersed*) if the coefficient of variation of the distribution of the times between failures is less than (greater than) 1. An extreme case of an underdispersed process is when the coefficient of variation is 0 (i.e., deterministic inter-event times), which yields a deterministic renewal process. The underdispersed process is much more regular in its event times.

Nonhomogeneous Poisson Processes

A nonhomogeneous Poisson process is another generalization of a Poisson process that allows for a failure rate $\lambda(t)$ (known as

the *intensity* function) that can vary with time.

Definition [11]. The counting process $\{N(t), t \geq 0\}$ is said to be a *nonhomogeneous Poisson process* (NHPP) with intensity function $\lambda(t)$, $t \geq 0$, if

1. $N(0) = 0$,
2. the process has independent increments,
3. $P(N(t+h) - N(t) \geq 2) = o(h)$, and
4. $P(N(t+h) - N(t) = 1) = \lambda(t)h + o(h)$,

where a function $f(\cdot)$ is said to be $o(h)$ if $\lim_{h \rightarrow 0} f(h)/h = 0$.

An NHPP is often appropriate for modeling a series of events that occur over time in a nonstationary fashion. Two common application areas are the modeling of arrivals to a waiting line (queueing theory) and the failure times of a repairable system (reliability theory) with negligible repair times. The cumulative intensity function,

$$\Lambda(t) = \int_0^t \lambda(\tau) d\tau \quad t > 0,$$

gives the expected number of events by time t , that is, $\Lambda(t) = E[N(t)]$. The probability of exactly n events occurring in the interval $(a, b]$ is given by

$$\frac{\left[\int_a^b \lambda(t) dt \right]^n e^{-\int_a^b \lambda(t) dt}}{n!}$$

for $n = 0, 1, \dots$ [23].

Random Process Generation

The algorithms presented in this section generate a sequence of random event times on the time interval $(0, S]$, where S is a real, fixed constant. If the next-event approach is taken for placing events onto the calendar in a discrete-event simulation model, then these algorithms should be modified so that they take the current event time as an argument and return the next event time. All processes are assumed to begin at time 0. The random

event times that are generated by the counting process are denoted by $T_1, T_2, \dots$, and random numbers (i.e., $U(0, 1)$ random variables) are denoted by U or $U_1, U_2, \dots$. These algorithms allow for the possibility that no events were observed on $(0, S]$.

Poisson Processes. Since the times between events in a Poisson process are independent and identically distributed exponential(λ) random variables, the following algorithm generates the event times of a Poisson process on $(0, S]$.

```

 $T_0 \leftarrow 0$ 
 $i \leftarrow 0$ 
while  $T_i \leq S$ 
   $i \leftarrow i + 1$ 
  generate  $U_i \sim U(0, 1)$ 
   $T_i \leftarrow T_{i-1} - \log(1 - U_i) / \lambda$ 
return  $T_1, T_2, \dots, T_{i-1}$ 

```

Renewal Processes. Event times in a renewal process are generated in a similar fashion to a Poisson process. Let $F_X(x)$ denote the cdf of the inter-event times $X_1, X_2, \dots$ in a renewal process. The following algorithm generates the event times on $(0, S]$.

```

 $T_0 \leftarrow 0$ 
 $i \leftarrow 0$ 
while  $T_i \leq S$ 
   $i \leftarrow i + 1$ 
  generate  $U_i \sim U(0, 1)$ 
   $T_i \leftarrow T_{i-1} + F_X^{-1}(U_i)$ 
return  $T_1, T_2, \dots, T_{i-1}$ 

```

Nonhomogeneous Poisson Processes. Event times can be generated for use in discrete-event simulation as $\Lambda^{-1}(E_1), \Lambda^{-1}(E_2), \dots$, where $E_1, E_2, \dots$ are the event times in a unit Poisson process [23]. This technique is often referred to as *inversion*, and is implemented below.

```

 $T_0 \leftarrow 0$ 
 $E_0 \leftarrow 0$ 
 $i \leftarrow 0$ 
while  $T_i \leq S$ 
   $i \leftarrow i + 1$ 
  generate  $U_i \sim U(0, 1)$ 
   $E_i \leftarrow E_{i-1} - \log(1 - U_i)$ 
   $T_i \leftarrow \Lambda^{-1}(E_i)$ 

```

```

return  $T_1, T_2, \dots, T_{i-1}$ 

```

The inversion algorithm is ideal when $\Lambda(t)$ can be inverted analytically, although it also applies when $\Lambda(t)$ needs to be inverted numerically. There may be occasions when the numerical inversion of $\Lambda(t)$ is so onerous that the *thinning* algorithm devised by Lewis and Shedler [10] might be preferable. This algorithm assumes that the modeler has determined a *majorizing* value λ^* that satisfies $\lambda^* \geq \lambda(t)$ for all $t > 0$.

```

 $T_0 \leftarrow 0$ 
 $i \leftarrow 0$ 
while  $T_i \leq S$ 
   $t \leftarrow T_i$ 
  repeat
    generate  $U \sim U(0, 1)$ 
     $t \leftarrow t - \log(1 - U) / \lambda^*$ 
    generate  $U \sim U(0, \lambda^*)$ 
  until  $U \leq \lambda(t)$ 
   $i \leftarrow i + 1$ 
   $T_i \leftarrow t$ 
return  $T_1, T_2, \dots, T_{i-1}$ 

```

The majorizing value λ^* can be generalized to a majorizing function $\lambda^*(t)$ to decrease the CPU time by minimizing the probability of “rejection” in the **repeat–until** loop.

All the stochastic process models given in this article are elementary. More complex models are considered in Nelson *et al.* [24].

CONCLUSIONS AND FURTHER READING

The discussion here has been limited to the generation of univariate random variates and stochastic processes. This only scratches the surface of the extensive literature in random variate generation. Other topics that might be of interest to the reader include algorithms for generating from specific distributions [1,3], such as the polar method for generating normal random variables; generating multivariate random variables [25]; generating autocorrelated arrival processes and correlated random vectors using the ARTA, NORTA, and VARTA methods [26]; generating lifetimes under the accelerated life and Cox proportional

hazards models [27,28]; generating combinatorial objects [1,29,30]; generating random matrices [31–36]; generating random polynomials [37]; shuffling playing cards [38]; generating random spawning trees [39, p. 379]; generating random sequences [40]; generating Markov chains [11,41–44]. An overview of the simulation methodology can be found by reading an introductory text, for example, Law [3] or Banks *et al.* [4], or the comprehensive overview in Henderson and Nelson [45].

RANDOMIZED SIMPLEX ALGORITHMS

BERND GÄRTNER
Institute of Theoretical Computer
Science ETH, Zurich, Switzerland

INTRODUCTION

Here is the simplest and probably the most natural randomized simplex algorithm: in each pivot step, choose the entering variable uniformly at random among all candidates. More precisely, if there are k candidates for the entering variable, throw a fair k -sided dice to select one among them. The pivot rule underlying this algorithm has been termed *Random-Edge*.

In general, we can think of a randomized simplex algorithm as having access to a stream of random bits that can be tapped at discretion. While *Random-Edge* taps the stream in every pivot step, there are also other meaningful ways. For example, the randomized least-index simplex algorithm randomly reshuffles variable indices in the beginning, and after that it always enters the candidate of smallest index in the reshuffled order.

The Geometric View

In order for the algorithm's behavior to be determined by the rule for choosing the entering variable, we have to assume that the leaving variable is always unique. Symbolic perturbation of the right-hand side, for example, takes care of this. In analyzing the complexity of randomized simplex algorithms, one often makes further simplifying assumptions that do not incur a loss of generality for theoretical purposes. The first such assumption is that the feasible region is bounded and nondegenerate so that it has the form of a *simple polytope*. Moreover, the objective function is assumed

to be *generic*, which geometrically means that no two polytope vertices have the same value. Finally, one assumes that the algorithm has access to some initial vertex of the polytope. (see ***Degeneracy and Variable Entering/Exiting Rules***).

In this geometric setting, the simplex method can be interpreted as a path following method on *polytope digraphs* (vertex-edge graphs of simple polytopes, with edge orientations induced by linear functions): While the current vertex is not the (unique) sink, go along some outgoing edge to a neighboring vertex. Starting from a standard-form linear program (LP) in n nonnegative variables and m equality constraints, we obtain a polytope with n facets in dimension $d := n - m$.

The term *Random-Edge* has been coined with the polytope digraph model in mind. Indeed, *Random-Edge* chooses among the outgoing edges uniformly at random in each step. There is a second well-studied randomized simplex algorithm called *Random-Facet* that is also easy to describe in the geometric setting: choose a facet F incident to the current vertex uniformly at random and recursively optimize over F first. If the sink v in F is not yet the global sink, traverse the unique outgoing edge at v and repeat the process from the vertex w thus reached.

Why Randomized Simplex Algorithms?

The theory of randomized simplex algorithms is concerned with the analysis of the *worst-case* expected behavior; that is, we want bounds for the expected number of steps that hold for *all* LPs in a given class. In contrast, average case analysis [1] and smoothed analysis [2] of the simplex method are about performance bounds for deterministic simplex algorithms that hold for *random* LPs (or more strongly, for all LPs after a small random perturbation in case of smoothed analysis). The message of smoothed analysis is that the “hard” linear programs are rare. With randomized simplex algorithms, we are also fighting against the hard ones.

The main motivation to study randomized simplex algorithms is the unsolved theoretical question whether there exists a simplex algorithm whose worst-case number of steps is polynomial in n and d . All known results pertaining to deterministic simplex algorithms are discouraging. Starting with the seminal work of Klee and Minty [3], almost all known deterministic simplex algorithms have been shown to require an exponential number of steps in the worst case, on polytopes as simple as deformed cubes [4] (see *The Simplex Method and Its Complexity*). Here, randomization makes a difference: there is a randomized simplex algorithm whose expected number of steps is always *subexponential* [5,6] and therefore smaller than any bound that can currently be proved in the deterministic setting. Derandomization techniques exist [7] but are currently unable to reproduce the subexponential bounds. An easier (but also unsolved) question is whether there is any linear programming algorithm at all that runs in *strongly* polynomial time, meaning that there is a polynomial runtime bound in terms of only n and d , but not the bitsizes of the input. Such a result would considerably strengthen the classic polynomial-time results for linear programming, due to Khachiyan and Karmarkar [8,9].

In this context, a second and related open question has attracted a lot of attention. Given a polytope P with n facets in dimension d and two vertices v and w of P , is there always a short path between v and w in the vertex-edge graph of P ? By short we mean polynomial in n and d . In graph-theoretic terms, we are talking about the diameter of the polytope graph. The famous Hirsch conjecture even stipulates that the diameter is always at most $n - d$, which is the best possible bound [10]. While the Hirsch conjecture has been proved for small values of d and $n - d$, and for many special classes of polytopes, the general conjecture has recently been falsified by Santos [11]. In order for any simplex algorithm to exhibit (expected) polynomial-time worst-case behavior, there must be a polynomial bound on the diameter. Interestingly, the currently best known *quasipolynomial*

diameter bounds are obtained from an (algorithmically intractable) derandomization of the subexponential randomized simplex algorithm [12,13]. Both the subexponential runtime bound and the quasipolynomial diameter bound are obtained in the polytope digraph model, without reference to the geometry of the underlying LP.

The aforementioned results have generated quite some excitement concerning randomized simplex algorithms back in the early 1990s; however, no substantial progress has been made since then. On the contrary, there are results [14,15] showing that it may be very difficult to beat the subexponential runtime bounds without exploiting more of the underlying geometry; and, how to do this is completely unclear. For the diameter problem, the situation is very similar [16].

Today, the randomized simplex algorithms are still considered a relevant theoretical tool in the context of the two unsolved questions above, but there is no indication that the desired strong polynomiality results are anywhere nearby. Research has consequently shifted focus away from linear programming. A major virtue of most randomized simplex algorithms is that they can easily be translated to related and/or more abstract settings where much less is known and the potential for new applications is higher.

In the subsequent three sections, we will review the major results that are known for randomized simplex algorithms on LPs and other optimization problems. With very few exceptions, all of these results pertain to either *Random-Edge* or *Random-Facet*.

THE RANDOM-EDGE SIMPLEX ALGORITHM

It is fair to say that the research on the *Random-Edge* simplex algorithm started with an erroneous exercise. In their book *Combinatorial Optimization: Algorithms and Complexity* [17, Chapter 8], Papdimitriou and Steiglitz discuss the famous *Klee–Minty cube*, a d -dimensional deformed cube on which the simplex algorithm with Dantzig’s original pivot rule may take $2^d - 1$ steps.

Problem 10 of Chapter 8 (marked as “relatively difficult”) asks the reader to prove that $O(d)$ steps suffice to solve the Klee–Minty cube with *Random-Edge*.

An upper bound of $O(d^2)$ is easy to get and was first shown by Kelly [18], who also conjectured a better bound of $O(d \log^2 d)$. But this conjecture (and therefore also the statement of Problem 10 of Ref. 17, Chapter 8 was later falsified by lower bounds of $\Omega(d^2/\log d)$ [19] and $\Omega(d^2)$ [20], thus showing that the easy upper bound of $O(d^2)$ on the performance of *Random-Edge* on the Klee–Minty cube is in fact tight.

Already the analysis of *Random-Edge* on the specific class of d -dimensional Klee–Minty cubes is nontrivial; coming up with matching upper and lower bounds on general polytopes seems out of reach with known techniques. Even for the class of combinatorial cubes, currently, the best upper bound is only slightly better than the trivial bound [21].

Specific results for specific classes of polytopes are available, though. Broder *et al.* have constructed a family of three-dimensional polytopes for which (the number of facets and) the expected number of steps is exponential in the height (length of the longest shortest-directed path from any vertex to the unique sink in the polytope digraph) [22]. This means that *Random-Edge* may take very long even though there is a short-directed path to the sink from every vertex. In the meantime, the performance of *Random-Edge* on three-dimensional polytopes is reasonably well understood [23]. For the special class of dual-to-cyclic four-dimensional polytopes, Gillman provides an analysis [24].

On d -polytopes with $d + 1$ facets (simplices), *Random-Edge* is easily seen to require an expected number of $\Theta(\log d)$ steps. For d -polytopes with $d + 2$ facets, the bound is $\Theta(\log^2 d)$, but this is already considerably harder to obtain [25]. No bounds are known for the case of $d + 3$ facets.

THE RANDOM-FACET SIMPLEX ALGORITHM

The name of this algorithm is connected to a remarkable historical coincidence. Independently, Matoušek *et al.* [6] as well as

Kalai [5] managed to prove that this algorithm has *subexponential* expected performance on all LPs. Even the proofs are very similar. A function in n and d is called *subexponential* if its logarithm is sublinear in both parameters. As a consequence, *Random-Facet* is the first (and still the only) simplex algorithm with better than exponential (expected) worst-case complexity. The main idea behind the subexponential analysis is simple and reveals itself most easily on combinatorial cubes [26,27].

The subexponential bound had another remarkable consequence: A clairvoyant version of *Random-Facet* (that knows the optimal random choices) can be used to prove a *quasipolynomial* bound on the diameter of polytope graphs [12,13]. This bound is still the best known today.

GENERALIZATIONS AND OTHER RANDOMIZED PIVOT RULES

Both *Random-Edge* and *Random-Facet* can be described and analyzed in terms of polytope digraphs. Actual coordinates of the polytope (that come from the underlying LP) are not needed. This is in contrast to most other pivot rules for the simplex method that base their decisions on reduced costs or other numerical data extracted from the LP.

As a consequence, *Random-Edge* and *Random-Facet* can be (and have been) used not only for linear programming, but also for related and more general optimization problems. Even prior to the subexponential bounds [5,6], Sharir and Welzl have introduced the abstract class of *LP-type problems* [28]. This class contains all LPs (after making the above-mentioned assumptions underlying the geometric view), but a number of other relevant optimization problems as well. Examples are the problem of computing the smallest enclosing ball of a set of points in d dimensions, or the problem of finding optimal strategies in simple stochastic games [26].

The *Random-Facet* algorithm and its subexponential bound extend to all LP-type problems [6,29]. In form of the very similar randomized least-index algorithm, *Random-Facet* even works for cyclic polytope digraphs that arise for example from

P-matrix linear complementarity problems and more generally, from the abstract class of *unique sink orientations*, see Ref. 30 and the references therein. It is open whether the subexponential bound holds in the cyclic setting. Abstract problem classes are also relevant in the context of *lower* bounds for the expected worst-case performance of randomized simplex algorithms. So far, all attempts at finding “bad” LPs for either *Random-Edge* or *Random-Facet* have been unsuccessful. No available evidence contradicts the possibility that both algorithms have polynomial expected worst-case runtime. But we at least know that in order to prove such a result, a simplistic digraph model is insufficient.

Both for *Random-Facet* [14] and for *Random-Edge* [15], there are hypercube digraphs (with all properties [31,32] that are needed to derive the known upper bounds on the expected performance), such that the respective algorithm needs a superpolynomial expected number of steps. The major limitation for the relevance of these results is that the “bad” digraphs that are being constructed are known not to come from any LPs, since they violate the necessary *Holt–Klee condition* [33]. An intriguing open question is whether (and how) the simplistic digraph model, enhanced with just the Holt–Klee condition, still allows for superpolynomial lower bounds. If we admit cycles in the model, *Random-Edge* may be exponentially slow even under the Holt–Klee condition [34].

As far as other randomized simplex algorithms are concerned, the literature is sparse. The *Random-Facet* simplex algorithm has been generalized by Kalai to the *Random-Face* algorithm, and Kalai actually conjectures polynomial runtime for appropriate parameters [13]. Joswig and Kaibel have proposed two new randomized simplex algorithms and analyzed their behavior on Klee–Minty cubes [35]. A randomized simplex-type algorithm has been shown by Kelner and Spielman to require expected polynomial time [36], but with a polynomial that also involves the bitsizes of the input.

The question whether there is a strong polynomial-time algorithm for linear programming is still open.

RECYCLING

ELIF AKÇALI

Department of Industrial and Systems
Engineering, University of Florida,
Gainesville, Florida

Increasing solid-waste generation rate worldwide is a growing concern for governments, environmental groups, and businesses. According to the Organization for Economic Cooperation and Development (OECD), increased prosperity, associated economic growth, and changes in consumption patterns contribute to the generation of higher rates of waste per capita. For instance, in the United States, the waste generation rate has increased from 2.68 to 4.62 pounds per day per capita from 1960 to 2007 [1]. During the same period, the recycling rate increased from about 6.4 to 24.9% in the country [1]. As industrial products are beginning to account for an increased fraction (from 11.3 to 17.9% by weight from 1960 to 2007 [1]) of the solid waste generated, the scope of the recycling industry in the United States, which was primarily limited to the recycling of glass, steel, aluminum, and paper products in the past, has been expanding to include the processing of a number of industrial durable products (e.g., appliances, cellular phones, and computers).

With the expanding scope and size of the recycling industry, operations research (OR) tools and techniques are being increasingly utilized for the optimization of recycling operations and the underlying reverse supply chain (RSC) systems. This article provides a general introduction to recycling and RSC systems and illustrates how OR methodologies can be used for the optimal design and operation of RSC systems for recycling. To this end, first, some of the issues encountered in recycling practice are highlighted, and a discussion of how these practical issues create some unique modeling challenges that necessitate the need to develop new analytical models for the design and operation of

RSC systems is presented. Second, an illustration of the use of OR techniques for the solution of an important pricing problem encountered in the context of RSC systems is provided. In this article, the term *recycling* is used in the broadest sense to include the recovery of materials and components for reuse wherever possible to avoid disposal, unlike remanufacturing (see the article titled **Remanufacturing** in this encyclopedia) that is primarily concerned with the recovery of products and components with the explicit intention to rebuild these products or reuse their components in their original design.

The remainder of this article is organized as follows. The section titled “Practical Issues in Recycling” provides a broader perspective on some of the practical issues encountered in the recycling industry. The section titled “Related Work” reviews the existing literature that address important planning and control problems that are encountered in the design and operation of RSC systems. The section titled “End-of-Life Vehicle Recycling” takes a closer look at the end-of-life vehicle recycling industry that motivates the work presented in this article. The section titled “Optimizing Price Decisions” illustrates how deterministic OR models can be utilized to address some important pricing decisions encountered in RSC systems. The section titled “Impact of Recovery Yield on Price Decisions” demonstrates how stochastic OR models can be used to investigate the influence of recovery yield uncertainty on the pricing decisions encountered in RSC systems. Finally, the last section provides a summary of the article and highlights future research directions.

PRACTICAL ISSUES IN RECYCLING

Upon a careful examination of the operations of a number of different recycling companies, several fundamental factors can be identified that influence the complexity of the

underlying RSC operations. In particular, the characteristics of the supply in the disposal market, the bill-of-material (BOM) structure of end-of-life products (ELPs), processing cost structures, and the demand in the reuse market pose different operational challenges.

Supply in the Disposal Market

The input to recycling is the supply of ELPs in the disposal market. Ideally, the collection process should control the *quantity*, *timing*, *composition*, and *quality (condition)* of the ELPs entering the RSC [2]. However, in practice, the ELPs can be received from either individual users one at a time (e.g., an individual may bring his/her used computer to a recycler) or a group of users in a batch (e.g., a large firm upgrading its entire computer network sends all used computers to the recycler). Similarly, a consumer may replace his/her cellular phone upon each airtime contract renewal, whereas another one may keep the same phone through a number of contract renewal cycles (Leff M. GRC Wireless Recycling, Inc., 2006. Personal communication). Hence, both the quantity and the timing of the ELPs entering the RSC *vary*. In addition, if a large firm upgrades its entire computer network and sells used computers to a recycler, this batch of ELPs may show little or no variation as to their make, model, age, and quality, that is, the composition of ELP supply is *homogeneous*. In contrast, a batch of products received from a third-party consolidator (e.g., a charity organization or an independent broker) may exhibit a lot of variation. For instance, Goodwill accepts all television set donations without making a distinction of the make, model, age, or quality of the set, and sells the inventory that cannot be liquidated through retail sales to recyclers. In this case, the composition of ELP supply is *heterogeneous*.

In the context of recycling, the quality of an ELP is associated with the economic value that can be recovered from it. The recoverable economic value depends on both the conditions under which the product was operated and whether any of the components of the product were removed or replaced during the course of its lifetime. For instance, an automotive engine that is driven in a cold climate

is subject to more wear and tear (due to extreme temperature changes), and hence, some of its components may not be recoverable. Therefore, the quality of the ELPs entering the RSC may exhibit a lot of *variation* and is *unknown* to the recycler until the products are disassembled.

For some product categories (e.g., cellular phones), recyclers are developing the capability to discriminate prices and selectively purchase ELPs, based on their make, model, age, and quality through product acquisition management [3,4]. As a result, *price-sensitive* markets are emerging, where the recyclers can exercise some control on the quantity, timing, composition, and quality of ELP supply.

BOM Structure of the ELP

Recycling entails the disassembly of an ELP to identify recoverable assets, and the BOM structure of the ELP has an influence on the disassembly operations used. First and foremost, BOM structure dictates the *nature* of disassembly, that is, *conserving* or *destructive*. Conserving disassembly preserves all of the components of the product, whereas destructive disassembly focuses on the recovery of certain components and may demolish some or all of the other components of the product. For instance, because of some irreversible operations (e.g., welding), disassembly may have to demolish some components of a product to recover a particular component. Similarly, BOM structure defines the *type* of the disassembly operation, that is, *dedicated* or *shared*. A dedicated operation retrieves a particular component, whereas a shared one releases multiple components simultaneously. Finally, disassembly operations may have precedence relationships that are dictated by the BOM structure of the ELP [5].

Processing Cost Structures

The nature of recycling operations as well as the characteristics of supply and demand impact the recycling cost structure. For instance, bulk material (e.g., ferrous metals) recovery processes exhibit significant differences in cost characteristics when compared to manual (e.g., cellular phone) recovery

processes. As bulk material recovery requires large amounts of input material to ensure overall equipment efficiency (Young S. CMC Recycling, 2007, personal communication), associated processing costs are largely volume dependent. Moreover, in bulk material recovery, the recycler may choose to collect a wider array of ELPs (e.g., scrap vehicles, household appliances) to stabilize the intermittent supply [6]. This, in turn, impacts the efficiency of the recovery process, that is, the same batch of material may have to be processed multiple times consecutively to improve the purity of the recovered material. Therefore, recycling costs may depend on the composition of the input stream, processing volume, and/or desired composition of the output stream.

Demand in the Reuse Market

The outputs of recycling are recovered materials and components that can be reused. The economic value associated with these outputs depends on the *quantity*, *quality*, and *timing* of recovery. That is, a recycler must ensure that the quantity of materials and components recovered must be sufficient to satisfy the demand in the reuse market. For instance, a steel manufacturer may refuse a transaction with a bulk metal recycler if the transaction involves an insufficient amount of material. Similarly, the quality of the recovered materials and components is important. For instance, a bulk metal recycler that processes plastic-coated copper wires has to take into account the trade-off between the cost of purifying the copper (i.e., stripping as much of the plastic as possible) and the revenue that he/she can collect. In addition, the timing of recovery is equally important, as it influences the revenue stream of the recycler.

The practical challenges explained above represent the distinguishing characteristics of the decision-making problems encountered in the context of RSC management for recycling. Hence, they lead to original and computationally challenging optimization problems that are not addressed by the traditional supply chain management literature. The section titled “Optimizing Price Decisions” demonstrates how deterministic OR models

can be used to determine the optimal ELP acquisition and reusable component selling prices. Later, the section titled “Impact of Recovery Yield on Price Decisions” illustrates how stochastic OR models can be utilized to investigate the impact of recovery yield rate on price decisions.

RELATED WORK

As we noted earlier, OR has made noteworthy contributions for the optimization of important design and control decisions encountered in RSC systems. Here, a brief overview of these contributions is presented. The analytical literature related to RSC systems for recycling primarily concentrate on network design, production planning, disassembly planning, and pricing problems. A detailed review of the existing work that focuses on network design, production planning, and disassembly planning is beyond the scope of this article. However, there are several papers and books that provide excellent reviews of the existing work in these areas [5,7–9].

With the increasing popularity of recycling and remanufacturing practices, ELPs are being sold and purchased as commodities and recyclers and remanufacturers are increasingly gaining market power to determine the purchase prices and exercise control on the supply quantity of used products [4]. Therefore, a recent stream of research investigates the pricing of recyclable ELPs and/or reusable recovered components. Considering settings where the supply of ELPs and/or the demand for reusable materials and components are price sensitive, several models that focus on determining the optimal prices have been proposed motivated by applications in reusable cellular phones [4], end-of-life vehicle recycling [10–12], and electronic product recycling [13]. With the exception of one study [10], where uncertain recovery yield is taken into account, the existing work focuses on the deterministic modeling of demand and/or supply [4,11–13]. In addition, while commercially available optimization software is used to obtain solutions for the proposed models [13], the majority of the work focuses on analyzing the structural properties of the optimal

solutions of the proposed models and develop efficient solution algorithms [4,10–12]. In the remainder of this article, some of these models studied by Karakayalı *et al.* [11,12], as well as Bakal and Akcali [10] are summarized to illustrate how deterministic and stochastic OR modeling and analysis techniques have been used to analyze these pricing decisions.

END-OF-LIFE VEHICLE RECYCLING

One of the complex industrial products that is processed by the recycling industry is automobiles. Each year around 15 million of vehicles reach the end of their useful service life in the United States. As more than 75% of an automobile's weight can be recycled in an economically viable manner by reusing its durable parts (e.g., engine, transmission, and catalytic converter) and recovering its reusable materials (e.g., ferrous and nonferrous metals), more than 95% of the retired vehicles are processed by automotive recyclers (i.e., parts dismantlers and scrap metal processors) [14].

Recyclers acquire end-of-life vehicles by purchasing them either at auctions or from final users who bring their vehicles for recycling [10,15]. Hence, the purchase price offered by a recycler influences the quantity of end-of-life vehicles acquired by the recycler and the recycler can increase the supply of end-of-life vehicles available by offering higher acquisition prices, that is, the supply is price sensitive. Moreover, recyclers may be willing to pay more for a two-year-old vehicle that is wrecked in a rear-end collision, since the front end of the car may still be intact from which several high-value parts can be recovered. Similarly, the recycler may be willing to pay less for a vehicle with aluminum engine and transmission, since the lighter weight castings are less durable (i.e., more susceptible to cracks), making them less likely to be remanufacturable than their traditional ferrous metal counterparts. Therefore, it is possible to classify end-of-life vehicles into multiple quality groups according to their age as well as their condition and offer different acquisition prices. Recyclers

typically perform several operations to ensure the environmentally safe disposal of end-of-life vehicles (see ***Closed-Loop Supply Chains: Environmental Impact*** for more information on the importance of environmental impact of supply chains) by removing all potentially hazardous liquids (e.g., gas, air conditioning gases, oils, coolants, and transmission and suspension fluids) and parts with hazardous materials (e.g., tires, airbags, and battery).

Then, the recycler may dismantle some parts from end-of-life vehicles for reuse or material recovery (e.g., transmission, engine, and catalytic converter). Moreover, the demand for the parts that can be remanufactured for reuse (e.g., transmission and engine) and parts that can be processed for material recovery (e.g., catalytic converter frame and facia components) can also be influenced through the selling prices. Finally, what is left of the end-of-life vehicles (i.e., the body along with parts that are not dismantled which is also known as the *hulk*) is shredded to recover reusable materials (e.g., ferrous and nonferrous metals). In this context, end-of-life vehicle recyclers may have the power to exercise control on either or both of these pricing decisions and have to characterize the acquisition prices of the end-of-life vehicles and the selling prices of the reusable automotive parts to align the supply in the disposal market with the demand in the reuse market.

Although the work reviewed in this article is primarily motivated by end-of-life vehicle recycling, the models and results summarized here can provide insights to a number of RSC systems for other complex industrial products. For instance, Aurora is engaged in disassembling processors from computers and selling them after a series of operations [16]. Similarly, GRC Wireless Recycling collects cellular phones and pagers from final users and sells them for reuse after minor modifications. (Leff M. GRC Wireless Recycling, Inc., 2006. Personal communication.) In the remainder of this article, the following generic problem is considered: given the parameters of supply functions for multiple types of quality groups of ELPs and demand

functions for multiple types of reusable components, our objective is to identify the optimal acquisition prices for the quality groups and optimal recovery quantities as well as the selling prices for the reusable components (or materials) to align the supply with the demand maximizing the net profit of the recycler.

OPTIMIZING PRICE DECISIONS

This section illustrates how deterministic OR models can be used to characterize the optimal acquisition and selling pricing decisions in RSC systems with price-sensitive ELP supply and reusable component demand markets. The following notation is used in the remainder of this section.

Sets and Indices

- $\mathcal{I}$ set of reusable components types indexed by i ; and
- $\mathcal{J}$ set of ELP quality groups indexed by j .

Parameters and Functions

- $D_i(p_i)$ demand of reusable component type i is a deterministic linear function of its selling price, that is, $D(p_i) = a_i - b_i p_i$ where $a_i, b_i \geq 0$;
- $S_j(f_j)$ supply of ELPs in quality group j is a deterministic linear function of its acquisition price, that is, $S(f_j) = \alpha_j + \beta_j f_j$ where $\alpha_j, \beta_j \geq 0$;
- c_j^d unit de-pollution cost per ELP in quality group j ;
- h_j unit salvage revenue per ELP (from which all reusable components are removed) in quality group j ;
- s_{ij} unit salvage revenue per reusable component type i recovered from an ELP in quality group j ;
- c_{ij}^p unit processing cost per reusable component type i recovered from an ELP in quality group j ;
- c_{ij}^r unit effective recovery cost associated with reusable component type i recovered from an ELP in quality group j , where $c_{ij}^r = s_{ij} + c_{ij}^p$; and

- κ_j unit effective salvage revenue associated with an ELP in quality group j where $\kappa_j = h_j + \sum_{i=1}^n s_{ij} - c_j^d$.

Decision Variables

- p_i unit selling price of the reusable component type i ;
- f_j unit acquisition price of the ELPs in quality group j ; and
- y_{ij} quantity of reusable components of type i recovered from ELPs in quality group j .

The profit maximization problem of the recycler can be modeled as follows:

$$\max \sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{J}} (p_i - c_{ij}^r) y_{ij} + \sum_{j \in \mathcal{J}} (\kappa_j - f_j)(\alpha_j + \beta_j f_j) \quad (1)$$

$$\text{subject to } y_{ij} \leq \alpha_j + \beta_j f_j \quad i \in \mathcal{I}, j \in \mathcal{J} \quad (2)$$

$$\sum_{j \in \mathcal{J}} y_{ij} = a_i - b_i p_i \quad i \in \mathcal{I} \quad (3)$$

$$- \alpha_j / \beta_j \leq f_j; \quad p_i \geq 0; \quad y_{ij} \geq 0 \quad i \in \mathcal{I}, j \in \mathcal{J}. \quad (4)$$

Note that objective function (1) maximizes the net profit of the recycler, which is given by the sum of the selling revenue obtained by selling reusable components, the salvaging revenue obtained by salvaging reusable components, and the salvaging revenue obtained by salvaging ELPs, that is, $\sum_{i \in \mathcal{I}} (p_i - c_{ij}^d, c_{ij}^p) (a_i - b_i p_i) + \sum_{j \in \mathcal{J}} (h_j - c_j^d - f_j) (\alpha_j - \beta_j f_j) + \sum_{i \in \mathcal{I}} \sum_{j \in \mathcal{J}} s_{ij} y_{ij} - (a_i - b_i p_i)$. Constraint set (2) ensures that the supply of ELPs collected in a particular quality group is larger than the quantity of reusable components recovered from that group. Constraint set (3) ensures that the demand for a reusable component type is equal to the total quantity of components recovered from all quality groups. Constraint set (4) defines the feasible values for the decision variables.

To consider the simplest problem environment with homogeneous supply (i.e., a single ELP quality group) and a single type

of reusable component, indices i and j can be dropped. In this case, it can be shown that Equation (1) is concave in p and f , and a closed-form solution can easily be characterized using its first-order optimality conditions as follows:

$$(f^*, p^*) = \begin{cases} \left(\frac{\kappa}{2} - \frac{\alpha}{2\beta}, \frac{c^r}{2} + \frac{a}{2b} \right) & \text{if } \frac{a-bc^r}{2} < \frac{\alpha+\beta\kappa}{2} \\ \left(\frac{a-\alpha+b(\kappa-c^r)}{2(\beta+b)} - \frac{\alpha}{2\beta}, \frac{a-\alpha-\beta(\kappa-c^r)}{2(\beta+b)} + \frac{a}{2b} \right) & \text{otherwise.} \end{cases}$$

Another problem setting of interest is concerned with homogenous supply and multiple types of reusable components. In this case, again it can be shown that Equation (1) is concave in f and p_i and the optimal prices can be determined in polynomial time. In addition, for the problem setting with heterogeneous supply (i.e., multiple ELP quality groups) and one type of reusable component, a polynomial time algorithm can be developed to determine the optimal prices. Finally, the problem setting with heterogeneous supply and multiple types of reusable components yields a concave quadratic maximization problem. An algorithm that exploits the structural properties of an optimal solution to the problem that converges quickly in practice can be developed [11,12]. In addition, see the section titled “Constrained Optimization” in this encyclopedia for more information on how to develop solution algorithms for constrained optimization problems.

It should also be noted that these models can easily be extended to decentralized settings where the collection and recovery activities can be performed by different agents. These extended models can be used to investigate when and why an OEM would outsource the collection or the recycling activity, that is, prefer a collector- or a recycler-driven channel, in the presence of environmental regulations that specify target ELP collection rates for the OEMs [11].

IMPACT OF RECOVERY YIELD ON PRICE DECISIONS

An important issue that further complicates the acquisition and selling pricing decisions

is the recovery yield. In practice, the fraction of reusable components that can be recovered for reuse from ELPs is typically random and may be dependent on the acquisition price in some cases. This section illustrates how stochastic OR tools can be used to investigate the impact of random recovery yield rate on acquisition and selling pricing decisions in RSC systems with price-sensitive supply and demand markets. See the article titled **Modeling Uncertainty in Optimization Problems** in this encyclopedia for more information on how to incorporate uncertainty into optimization problems.

To this end, two cases can be considered both of which are motivated from real-life applications end-of-life vehicle recycling where the yield rate is random. Some salvagers purchase end-of-life vehicles at auctions. Once recoverable components are harvested, and yield is realized from the supply of end-of-life vehicles, the recycler sets the price and sells the reusable automotive parts. In this case, the recycler has the opportunity to adjust the selling price for the reusable automotive part to match the supply with the demand. In some cases, however, a part buyer contacts the recycler requesting a particular part and the recycler and the buyer agree on the sales price. Then, the recycler purchases end-of-life vehicles to satisfy the demand. If the yield is not enough to cover the demand, then the recycler is still bound by the price decision made *a priori*, and may have to incur a penalty for the unsatisfied demand in addition. In this case, the recycler does not have the opportunity to adjust the sales price after realizing the yield.

Let R be a random variable that represents the maximum attainable recovery yield rate and r a realization of R . Also, let $g(r)$ and $G(r)$ denote the probability distribution function and cumulative distribution function of random variable R , respectively. Moreover, as the recycler increases the acquisition price, ELPs in better condition becomes available to the recycler, which in turn can be interpreted as a higher probability of recovering a reusable component from the ELP. Let this probability of recovering a reusable component be represented by $t(f)$, which is a concave, nondecreasing function of f and

converges to 1 as f increases. Then, for the two cases discussed above, following models can be formulated:

Postponed Pricing Model (PPM)

In this setting, the recycler can postpone the decision to characterize the selling price for the reusable component until after the realization of the recovery rate of the ELPs. More specifically, the pricing decisions are made in two stages (see the section titled “Two-stage Stochastic Programming” in this encyclopedia). First, the acquisition price of the ELPs is identified and the corresponding supply is collected. After the realization of the recovery rate, selling price for the reusable component is determined, and demand is observed in the second stage. Note that the recycler never faces lost sales for the reusable component; demand for the reusable component can be aligned with the available supply by adjusting the selling price accordingly.

First, the second-stage decision is analyzed. Given the acquisition price, f , and recovery yield rate realization, r , the second-stage problem for the recycler reduces down to determining the selling price for the reusable component to maximize the total net profit. Then, the profit maximization problem can be formulated as follows:

$$\max (p - c^r)(a - bp) + (\kappa - f)(\alpha + \beta f) \quad (5)$$

$$\text{subject to } a - bp \leq rt(f)(\alpha + \beta f). \quad (6)$$

Given the acquisition price and recovery yield rate realization, the optimal selling price for the reusable component can be characterized as follows:

$$p^* = \begin{cases} \frac{a}{2b} + \frac{c^r}{2} & r \geq \frac{\ell}{t(f)(\alpha + \beta f)} \\ \frac{a - rt(f)(\alpha + \beta f)}{b} & r < \frac{\ell}{t(f)(\alpha + \beta f)} \end{cases}, \quad (7)$$

where $\ell = (a - bc^r)/2$.

Now, the first-stage decision can be analyzed. Given the optimal selling price for the reusable component obtained from the analysis of the second stage and the realization of

the recovery yield rate, the profit maximization problem faced by the recycler in the first stage can be formulated as follows:

$$\begin{aligned} \Pi(f|R=r) &= \begin{cases} \frac{\ell^2}{b} + (\alpha + \beta f)(\kappa - f), \\ r \geq \frac{\ell}{t(f)(\alpha + \beta f)}; \\ t(f)r(\alpha + \beta f)\frac{2\ell - t(f)r(\alpha + \beta f)}{b} \\ + (\alpha + \beta f)(\kappa - f), & r < \frac{\ell}{t(f)(\alpha + \beta f)}. \end{cases} \end{aligned}$$

Taking expectation with respect to R yields

$$\begin{aligned} E[\Pi(f)] &= \int_0^{\ell/(t(f)(\alpha + \beta f))} t(f)r(\alpha + \beta f) \\ &\times \frac{2\ell - t(f)r(\alpha + \beta f)}{b} g(r) dr \\ &+ \int_{\ell/(t(f)(\alpha + \beta f))}^1 \frac{\ell^2}{b} g(r) dr + (\alpha + \beta f)(\kappa - f). \end{aligned} \quad (8)$$

The objective function (8) is concave in the acquisition price for the ELPs, and its optimal value can be determined numerically. That is, the recycler determines the optimal acquisition price for the ELPs optimizing the expected profit function (8) and collects the resulting supply of ELPs. After the realization of the random recovery yield rate, selling price of the reusable components can be characterized using Equation (7).

Simultaneous Pricing Model (SPM)

In this case, the recycler has to determine the acquisition and selling prices simultaneously. That is, both acquisition and selling prices must be specified before the realization of the random recovery yield rate. Hence, the recycler may not be able to cover the demand for the reusable components entirely. Therefore, the profit function can be modified to include a term to account for the unsatisfied demand. Let v denote the unit penalty cost for unsatisfied demand (or the unit cost of supply from an outside source to satisfy the demand). Given any realization of the random recovery yield, the profit function of the

recycler is given by

$$\Pi(f, p|r) = \begin{cases} (p - c^r)(\alpha - bp) + (\kappa - f)(\alpha + \beta f), & r \geq \frac{a-bp}{t(f)(\alpha+\beta f)}; \\ t(f)r(\alpha + \beta f)(p - c^r) - v(a - bp - t(f)r(\alpha + \beta f)), & r < \frac{a-bp}{t(f)(\alpha+\beta f)}. \\ + (\alpha + \beta f)(\kappa - f), \end{cases}$$

Taking expectation with respect to R and rearranging the terms yields

$$\begin{aligned} E[\Pi(f, p)] &= \int_0^{\frac{a-bp}{t(f)(\alpha+\beta f)}} [rt(f)(\alpha + \beta f)(p - c^r + v) \\ &\quad - v(a - bp)] g(r) dr \\ &\quad + \int_{\frac{a-bp}{t(f)(\alpha+\beta f)}}^1 (a - bp)(p - c^r) g(r) dr \\ &\quad + (\alpha + \beta f)(\kappa - f). \end{aligned} \quad (9)$$

It can be shown that Equation (9) is pseudoconcave in f and p separately. However, it is analytically challenging to show that the Hessian of Equation (9) is strictly positive. Upon extensive numerical analysis with a variety of distribution functions, it can be conjectured that Equation (9) is pseudoconcave. This allows for to use first-order conditions of Equation (9) to obtain a local maximum and treat it as the global optimum in the remainder of our analysis.

Using these analytical results for PPM and SPM, it is possible to investigate the influence of recovery yield rate on the pricing decisions of a recycler. Results from a comprehensive computational analysis reveal that this influence critically depends on the profit margin associated with the reusable component. If the hulk and component salvage value for the component is high, which can be referred to as a *high-margin component*, then the recycler would not make any effort into increasing the recovery yield rate, if it is beyond a certain threshold. However, if the hulk and component salvage values of the component are low, which can be referred to as a *low-margin component*, then the recycler's profit would increase by increasing the recovery yield rate. Moreover, it is possible

to observe that the quantities of ELPs acquired and reusable components sold are higher for high-margin components under both pricing models. A comparison of the pricing models further reveals that as PPM always yields higher profits than SPM, as it provides the recycler with the opportunity to adjust the selling price after the realization of the random recovery yield, that is, suffer less from the effects of random recovery yield. Furthermore, there are no significant differences in expected profit under PPM and SPM for high-margin components, and the difference diminishes as the mean yield rate increases. In addition, profits generated in both models decrease as the standard deviation of the yield rate increases, and the benefits of PPM over SPM become more pronounced as the standard deviation increases. Finally, for low-margin components, the expected profit under PPM is higher than that under SPM, and the difference does not diminish as the mean yield rate increases. Hence, postponing the pricing decision is always more beneficial for the recycler, and the expected benefit is higher for lower yield rates, higher yield variability, and lower margin components. Using SPM, it is also possible to investigate the value of partial or perfect recovery yield rate information [10].

CONCLUDING REMARKS

This article illustrated how OR models can be utilized for the solution of important planning and control problems encountered in RSC systems for recycling. To this end, a brief introduction of some of the issues encountered in recycling practice that influence the complexity of the planning and control problems is provided. Specifically, a discussion of the characteristics of the supply in the disposal markets, the bill-of-materials structure of the ELPs, the processing cost structures, and the demand in the reuse markets is presented. Then, motivated by end-of-life vehicle recycling, a relatively simple setting is considered, where the supply in the disposal market can be modeled as a deterministic linear function of the acquisition price of the

ELP, the ELP has a simple BOM structure, the processing costs can be modeled as linear function of the quantity of ELPs processed, and the demand in the reuse market is also a deterministic linear function of the selling price of the reusable component. First, some deterministic OR models are developed to determine the optimal ELP acquisition and reusable component selling prices in RSC systems. Then, some simple stochastic OR models are developed to investigate the yield uncertainty on the pricing decision encountered in RSC systems. Future research in this area that takes the practical issues discussed in the section titled "Related Work" into account explicitly may have significant impact on some of the many challenging problems that arise in the context of RSC management.

REDUCTION OF A POMDP TO AN MDP

BURHANEDDIN SANDIKÇI
Booth School of Business,
University of Chicago,
Chicago, Illinois

A Markov decision process (MDP) is a standard mathematical tool for modeling, analyzing, and ultimately solving many sequential decision-making problems under uncertainty (see “*Introduction to MDPs*” for an introduction to MDPs). Many excellent texts [1–4] discuss MDP theory and its applications in a wide variety of settings in great detail. One of the key assumptions in an MDP model is that the *state* of the underlying process is *perfectly* known to the decision maker at all decision epochs. However, in many real-life situations, the nature of the situation being modeled may not allow the decision maker to completely observe the state of the underlying process or acquiring perfect state information may be too costly, in which case, a completely observable MDP model would no longer apply. Relaxing the perfect state information assumption in an MDP model yields to what is known as a “*partially observable Markov decision process (POMDP)*” model (also see ***Partially Observable MDPs (POMDPs): Introduction and Examples***”).

Examples of application domains where POMDPs are utilized include machine maintenance and replacement [5–10], inventory control [11], inspection of structural units such as paved roads, bridges, and buildings [12], network troubleshooting [13], search for a moving object [14,15], medical diagnosis and treatment [16–19], health care systems analysis [20], optimal design of questionnaires when the answers are not truthful [21], optimal teaching strategies [22], and fisheries [23]. We refer the reader to [24–26] for detailed reviews of POMDP applications.

The seemingly innocent relaxation of the assumption of perfect state information to

noise-corrupted state information comes at a significant cost in complexity. The so-called *curse of dimensionality* [1], which can be summarized as the exponential increase in the amount of resources (data, time, computing memory, and so on) needed to incorporate an extra dimension to the model, is a major computational burden in using the dynamic programming based approaches (see “*Dynamic Programming*” for deterministic dynamic programs) in many settings. This curse coupled with the stochastic elements in an MDP model further restricts the solvability of such models in practice.

Analyzing the structural properties of an MDP model, which oftentimes includes proving the existence of structured optimal policies (and value functions), is crucial to accelerate the solution speed and therefore to partially overcome this computational burden (also see “*Structured MDP Policies*”). Structural analyses of POMDP models, however, are usually much harder than their MDP counterparts, exactly because of the limited observability of the state of the process. As a result, in general, there is little hope to solve POMDP models through exploiting special structures. (Of course, if found, some special structures may help solve certain problems, but the main difficulty is identifying them.)

The exact algorithms [26–33] for POMDPs have not yet proved extremely useful for solving practical problems. The current literature reports solutions of POMDP models with only a few states (typically <10) using one of the exact algorithms. Given the scarcity of efficient exact methods to solve POMDPs, several approximation methods have been developed. Surveys of exact and approximate algorithms for POMDPs are available in Refs 26, 34, and 35.

Grid-based approximations are the most natural and widely used techniques to find approximate solutions to POMDPs. These techniques sample a finite number of points, called the *grid*, from the entire state space, compute the (approximate) value of the

points in the grid using only the points in the grid and approximate the values of the non-grid points (i.e., those points that are in the state space but not selected to the grid) from the computed grid points' values via some form of interpolation. Several variations exist in the literature [19, 36–39]. Grid-based approximations usually do not have any performance guarantees, therefore they should be viewed as heuristics. In this article, we summarize main results associated with approximating POMDP problems via (variants of) completely observable MDPs.

The rest of this article is organized as follows. We begin with a brief review of completely observable MDPs and continue with an analogous overview of POMDPs. Next, we discuss the main difficulties in solving POMDP models and compare how the completely observable MDP approximates the optimal value function of a POMDP model. Furthermore, we provide a concise description of grid-based approximation methods for POMDPs and compare the grid-based values to the exact values and show that grid-based values provide better estimates than the values obtained by completely ignoring partial observability. Finally, we also show how linear programming may be used to obtain tightest possible grid-based approximations.

MARKOV DECISION PROCESSES

We consider a sequential decision-making problem under *uncertainty*, where a decision maker can *control* the flow of the system at *discrete time* points $1, \dots, T$, called *decision epochs*. Note that T need not be finite. At any given decision epoch t , the system occupies a *core state* i that takes values from the *core state space* S . We assume that the actual state of the system, i , is completely known to the decision maker when a decision is to be made. We relax this assumption in the next section. The decision maker has control over the system by modifying its trajectory through choosing an *action* a from the *action space* $\mathcal{A}$ at each decision epoch t . We assume that S and $\mathcal{A}$ are both discrete finite sets. (We could generalize this setup to allow time-dependent state and action spaces, namely,

S_t and $\mathcal{A}_t$. However, this would not change the basic results presented in this article, hence we choose to drop the time index t from these sets for notational simplicity.) Uncertainty in the system is governed by its probabilistic evolution; that is, when the system is in state $i \in S$ and the decision maker chooses action $a \in \mathcal{A}$ at decision epoch t , the state of the system in the next decision epoch $t + 1$ becomes $j \in S$ with probability $p_{ij}^{a,t} \equiv P(j|i, a)$. The fact that the next state of the system is only dependent on the current state and action is called the *Markovian property* of the process. Furthermore, as a result of choosing action $a \in \mathcal{A}$ while the system is in state $i \in S$ at time t , the decision maker receives an *immediate reward* $r_t(i, a)$. The collection of objects $(T, S, \mathcal{A}, P\{\cdot|\cdot, \cdot\}, r(\cdot, \cdot))$ is referred to as a *completely observable Markov decision process*.

The objective of the decision maker is to identify a decision-making *policy* that maximizes the *expected total discounted reward* over the course of the entire process

$$\mathbb{E} \left[\sum_{t=0}^{T-1} \lambda^t r_t(i, a) \right], \quad (1)$$

where $\lambda \in [0, 1)$ is the discount rate. Other optimality criteria such as maximizing the expected total reward (see “*Total Expected Reward Criterion*”) or maximizing the average reward (see “*Average Reward Criterion*”) can also be handled.

For an infinite-horizon problem ($T = \infty$), a stationary model (i.e., a model in which the parameters do not change over time) is a standard assumption in the literature. Following this assumption, we drop the time index t for the infinite-horizon models presented in this article. An optimal policy that maximizes the expectation in Equation (1) can be found by solving the following set of recursive equations [3]:

$$u^*(i) = \max_{a \in \mathcal{A}} \left\{ r(i, a) + \lambda \sum_{j \in S} p_{ij}^a u^*(j) \right\} \quad \text{for } i \in S, \quad (2)$$

where $u^*(i)$ is the optimal MDP value function in state $i \in S$. The optimal action

$a^*(i)$ for state $i \in S$ is chosen as the argument $a \in \mathcal{A}$ that maximizes the right-hand side of Equation (2). *Value iteration* (see **Total Expected Discounted Reward MDPs: Value Iteration Algorithm**), *policy iteration* and its variants (see **Total Expected Discounted Reward MDPs: Policy Iteration Algorithm**) are typical exact algorithms used to solve the optimality equations (Eq. 2).

For a finite-horizon problem ($T < \infty$), the analog of Equation (2) can be written as

$$u_t^*(i) = \max_{a \in \mathcal{A}} \left\{ r_t(i, a) + \lambda \sum_{j \in S} p_{ij}^{a,t} u_{t+1}^*(j) \right\} \quad \text{for } i \in S; \quad t = 1, \dots, T-1, \quad (3)$$

with boundary conditions

$$u_T^*(i) = r_T(i) \quad \text{for } i \in S, \quad (4)$$

where $u_t^*(i)$ is the optimal MDP value function in state $i \in S$ when there are $T-t$ decision epochs left until the end of the horizon and $r_T(i)$ represents the terminal reward received when the process is in state i at the end of the planning horizon. The optimal action $a_t^*(i)$ at each decision epoch $t = 1, \dots, T$ for state $i \in S$ is chosen as the argument $a \in \mathcal{A}$ that maximizes the right-hand side of Equation (3). The *backward induction* algorithm provides an efficient and exact method for solving the optimality equations (Eq. 3).

PARTIALLY OBSERVABLE MARKOV DECISION PROCESSES

We consider the same problem described in the previous section. However, we now relax the completely observable system state assumption. That is, we allow partial observability that yields imperfect state information. As a result, the system does not directly reveal its actual state $j \in S$, rather the decision maker observes a signal k , which takes values from the *observation set* $\mathcal{Z}$ and relates to the core state $j \in S$ through the *observation probability* $q_{jk}^{a,t} \equiv Q\{k|j, a\}$. More precisely, the observation probability $q_{jk}^{a,t}$ denotes the probability that the decision maker receives signal k at time

$t+1$ while the system actually occupies state j at time $t+1$ after action a was taken at time t . We assume that $\mathcal{Z}$ is a discrete finite set. The collection of objects $\langle T, S, \mathcal{A}, P\{\cdot|\cdot, \cdot\}, r(\cdot, \cdot), \mathcal{Z}, Q\{\cdot|\cdot, \cdot\} \rangle$ is referred to as a *partially observable* Markov decision process. Note that all but the last two objects in this collection are identically shared with completely observable MDPs.

It would no longer be useful to write the optimality equations for this new system using the core states, because they are not observable. However, we can write the optimality equations using a new concept called *belief state* and still possess the Markovian property, because a belief state is known to be a *sufficient statistic* for the entire history of the process [40,41]. This result implies that the probability of being in a particular belief state at time t is only dependent on which belief state was occupied at time $t-1$ and not on any of the previous belief states, hence the Markovian property holds. A belief state π is defined to be a probability distribution over the set of core states S , where the i th component of π , denoted by π_i , represents the probability of being in core state $i \in S$. Let $|S| = m$ and $\Pi(S)$ be the set of all probability distributions over S (also called the $(m-1)$ -dimensional probability simplex or sometimes referred to as the *belief simplex*), that is,

$$\Pi(S) = \left\{ \pi \in \mathbb{R}^m : \sum_{i=1}^m \pi_i = 1, \quad \pi_i \geq 0 \quad \forall i \right\}.$$

Note that there are infinitely many probability distributions that could be defined over S when $m \geq 2$. Therefore, a POMDP model defined over belief states has infinitely many states, which causes serious computational challenges.

Also note that a belief state POMDP model is equivalent to a completely observable MDP model with a continuous state space. We could, in theory, use the techniques available for continuous state MDPs to solve belief state POMDPs. However, it is usually more efficient to take advantage of the special

structure of the state space, which is not an arbitrary continuous space but rather it is a space composed only of discrete probability distributions.

As we will write the optimality equations using belief states, we need to know how to make transitions among belief states. For this purpose, let π be the current belief state and assume that action $a \in \mathcal{A}$ is taken while in this belief. As a result of this action, during the next decision epoch, the system occupies a (potentially new) *core* state, which is not known to the decision maker with certainty because it is not observable. Instead, the decision maker observes a signal $k \in \mathcal{Z}$ for this new decision epoch and needs to update her prior belief π using the information that just became available. The j th component of the updated belief state π' , denoted by π'_j , can be computed by [24]

$$\pi'_j = \frac{\sum_{i \in \mathcal{S}} \pi_i p_{ij}^a q_{jk}^a}{\sum_{i \in \mathcal{S}} \sum_{\ell \in \mathcal{S}} \pi_i p_{i\ell}^a q_{\ell k}^a}, \quad (5)$$

which is derived using Bayes' formula and simple probability arguments (see, for example, Ref. 26 for a detailed derivation of this formula.) Note that although π' depends on π , k , and a , we suppress this dependency on the left-hand side of Equation (5) for notational clarity. Also note that we drop the time index t from Equation (5) for notational clarity.

For an infinite-horizon problem ($T = \infty$), an optimal policy that maximizes the expectation in Equation (1) can be found by solving the following set of recursive equations [24,26]:

$$\begin{aligned} v^*(\pi) &= \max_{a \in \mathcal{A}} \left\{ \rho(\pi, a) + \lambda \sum_{i \in \mathcal{S}} \sum_{j \in \mathcal{S}} \sum_{k \in \mathcal{Z}} \pi_i p_{ij}^a q_{jk}^a v^*(\pi') \right\} \\ &\text{for } \pi \in \Pi(\mathcal{S}), \end{aligned} \quad (6)$$

where $v^*(\pi)$ is the optimal POMDP value function for belief state $\pi \in \Pi(\mathcal{S})$ and $\rho(\pi, a) = \sum_{i \in \mathcal{S}} \pi_i r(i, a)$. The optimal action

$a^*(\pi)$ for state $\pi \in \Pi(\mathcal{S})$ is chosen as the argument $a \in \mathcal{A}$ that maximizes the right-hand side of Equation (6).

For a finite-horizon problem ($T < \infty$), the analog of Equation (6) can be written as [26,42]

$$\begin{aligned} v_t^*(\pi) &= \max_{a \in \mathcal{A}} \left\{ \rho_t(\pi, a) \right. \\ &\quad \left. + \lambda \sum_{i \in \mathcal{S}} \sum_{j \in \mathcal{S}} \sum_{k \in \mathcal{Z}} \pi_i p_{ij}^{a,t} q_{jk}^{a,t} v_{t+1}^*(\pi') \right\} \\ &\text{for } \pi \in \Pi(\mathcal{S}); \quad t = 1, \dots, T-1, \end{aligned} \quad (7)$$

with boundary conditions

$$v_T^*(\pi) = \sum_{i \in \mathcal{S}} \pi_i r_T(i) \quad \text{for } \pi \in \Pi(\mathcal{S}), \quad (8)$$

where $v_t^*(\pi)$ is the optimal value function in state $\pi \in \Pi(\mathcal{S})$ when there are $T - t$ decision epochs left until the end of the horizon. The optimal action $a_t^*(\pi)$ at each stage $t = 1, \dots, T$ for state $\pi \in \Pi(\mathcal{S})$ is chosen as the argument $a \in \mathcal{A}$ that maximizes the right-hand side of Equation (7).

APPROXIMATING A POMDP BY AN MDP

As we have seen in the previous section, a POMDP is a generalization of a completely observable MDP with an enlarged state space called the *belief space*, that is, the space of all probability distributions over the set of core states. Although this belief space allowed us to nicely recast the POMDP as a completely observable MDP, it is the source of the main difficulty when solving a POMDP model, because the dynamic programming recursions needed to solve a belief state POMDP is equivalent to having infinitely many equations with infinite number of variables. Evaluating the optimality equations over the entire belief space, therefore, suffers from computational tractability. Indeed, the current state of the art in the POMDPs can exactly evaluate these optimality equations only for problems with very few core states (typically considered toy problems) [31,43].

Approximation methods have been developed to partially overcome the computational challenges for POMDPs in exchange for forsaken optimal solutions. Grid-based approximations are the most frequently encountered methods in the literature. Grid-based approaches, as we will see below, have no performance guarantees in general, therefore they should be viewed as *heuristic* approximations at best and one-sided bounds obtained from such approaches should be treated with caution. Throughout the rest of this article, we focus on infinite-horizon problems for notational simplicity, but similar results can be easily written for finite-horizon problems as well.

Approximating with a Completely Observable MDP

We start with the simplest approximation method that can be viewed as a special type of grid-based technique. Ignoring the partial observability inherent in the system and solving the POMDP problem as if its states are completely observed is the simplest of all approximations and not an infrequent one in many real problems. In this approach, one recursively solves Equations (2) to obtain the optimal MDP value functions $u^*(i)$ for each core state $i \in \mathcal{S}$. For a given belief state $\pi \in \Pi(\mathcal{S})$, one can estimate the optimal POMDP value function $v^*(\pi)$ by

$$\hat{u}(\pi) = \sum_{i \in \mathcal{S}} \pi_i \cdot u^*(i). \quad (9)$$

When the belief state π is chosen to be one of the extreme points of the belief simplex, we denote it by the i th unit vector $\mathbf{e}^i$, which assigns 1 to its i th position and 0 elsewhere. Such a belief state is essentially equivalent to occupying core state i in a completely observable system. For any $i \in \mathcal{S}$, using $u^*(i)$ as an approximation for $v^*(\mathbf{e}^i)$ overestimates the true value [19,44], that is $v^*(\mathbf{e}^i) \leq u^*(i)$. Therefore, the approximation given in Equation (9) would overestimate the true value for arbitrary belief states, that is

$$v^*(\pi) \leq \hat{u}(\pi) \quad \text{for } \pi \in \Pi(\mathcal{S}). \quad (10)$$

Intuitively, inequality (10) implies that we cannot do any worse if we had access to complete state information and therefore the difference $\hat{u}(\pi) - v^*(\pi)$ can be interpreted as the value of accessing full information from the current partial information.

Approximating with a General Grid

In this section, we address the partial information availability by forming a grid composed of a finite number of sampled belief states from the entire belief simplex. Given a list of grid points, we recursively solve equations similar to Equation (6) adjusted for the finite number of states (or, alternatively, similar to Equation (2) adjusted for partial observability). We still need to resolve an additional difficulty: because of the finite sample, during the solution process, a point in the grid may be updated to a point not included in the grid by the Bayesian updating formula given by Equation (5). In such a case, the value associated with the nongrid point is estimated by some form of interpolation of the values of the grid points.

As a general rule, the limited (computational) resources should be wisely devoted to potentially useful belief points. In other words, one should refrain from including points that are highly unlikely to be reached during the solution process, because the contribution of such points would be negligibly small when taking the expectation in the recursive equations. Furthermore, assume that all the corner points of the probability simplex are already included in the grid. Note that there would be m corner points in an $(m - 1)$ -dimensional probability simplex. Let $\mathcal{G}$ denote the entire grid and $|\mathcal{G}| = n \geq m$.

Beyond these assumptions, there are several ways of forming and managing the grid. We briefly mention the most common of these approaches and note that our discussion below is independent of the grid management approach (except the fact that it must include all the corner points of the simplex.) A *fixed-resolution regular grid* samples points from the belief simplex in regular intervals (i.e., equidistant points in each dimension of the simplex) and does not vary these points throughout the rest of the solution process [36]. The advantage of this

method is its efficient interpolation, whereas the obvious disadvantage is the exponential growth in the size of the grid as the number of core states or the resolution of the grid increase [19,39,44]. A *variable-resolution irregular grid* samples points from the belief simplex in irregular intervals and adds/removes to/from the grid over iterations as perceived necessary by heuristic rules [37,38]. The advantage of this method is its more economic use of grid points in approximating the value function, whereas its disadvantage is inefficient interpolation times. A *variable-resolution regular grid* [39] and a *fixed-resolution irregular grid* [19] are additional methods that try to take advantage of the strong aspects of the previous two methods. Further details on grid-based methods can be found in Refs 34, 39, and 44 and the references therein.

The Approximation Function. We now derive the recursive equations to be solved with this approach. Because all the corner points of the belief simplex are included in grid $\mathcal{G}$, any belief point π from the simplex can be written as a convex combination of the points in $\mathcal{G}$, that is,

$$\pi = \sum_{\ell=1}^n \beta_\ell \mathbf{b}^\ell, \quad (11)$$

where $\mathbf{b}^\ell \in \mathcal{G}$ and $\beta_\ell \geq 0$ for $\ell = 1, \dots, n$, and $\sum_{\ell=1}^n \beta_\ell = 1$.

We compute the grid-based approximate value function $\hat{v}(\cdot)$ associated with a belief state $\mathbf{b} \in \mathcal{G}$ using a modified version of the POMDP optimality equations (Eq. 6). When we write the optimality Equation (6) for a given belief state $\mathbf{b} \in \mathcal{G}$, the problem will arise on the right-hand side as we will need the value associated with the updated belief vector, denoted by $\mathbf{b}'$, which is not known if $\mathbf{b}' \notin \mathcal{G}$. However, we can estimate the value associated with $\mathbf{b}'$ using a convex combination of the known values of the grid points $\mathbf{b} \in \mathcal{G}$. That is, replacing $v^*(\mathbf{b}')$ on the right-hand

side of Equation (6) with a convex interpolation estimate $\sum_{\ell=1}^n \beta_\ell \hat{v}(\mathbf{b}^\ell)$ yields the grid-based approximation

$$\begin{aligned} \hat{v}(\mathbf{b}) = \max_{a \in \mathcal{A}} & \left\{ \rho(\mathbf{b}, a) \right. \\ & \left. + \lambda \sum_{i \in S} \sum_{j \in S} \sum_{k \in \mathcal{Z}} b_i p_{ij}^a q_{jk}^a \sum_{\ell=1}^n \beta_\ell \hat{v}(\mathbf{b}^\ell) \right\} \\ & \text{for } \mathbf{b} \in \mathcal{G}. \end{aligned} \quad (12)$$

It should be noted here that some researchers use heuristic rules such as rounding or using the K nearest neighboring grid points (for some arbitrary positive integer K) to find the value of a nongrid point. Unfortunately, such heuristics do not work as intended in general when $m \geq 3$. The main reason for the failure of such heuristics is the fact that the nongrid point under consideration is not guaranteed to be spanned by the grid points found by such rules.

It can be shown that [19] the grid-based approximation given in Equation (12) yields identical results to the solution of the completely observable MDP for the corner points of the belief simplex (i.e., $\hat{v}(\mathbf{e}^i) = u^*(i)$ for $i \in S$) and that [19,44] the grid-based value also overestimates the true value, that is

$$v^*(\mathbf{b}) \leq \hat{v}(\mathbf{b}) \quad \text{for } \mathbf{b} \in \mathcal{G}. \quad (13)$$

More importantly, the grid-based value provides a better upper bound for the true value than the completely observable MDP value [19], that is

$$\hat{v}(\mathbf{b}) \leq \hat{u}(\mathbf{b}) \quad \text{for } \mathbf{b} \in \mathcal{G}. \quad (14)$$

It can further be shown that inequalities (Eqs 13 and 14) hold for $\pi \in \Pi(S) \setminus \mathcal{G}$. The difference $\hat{u}(\mathbf{b}) - \hat{v}(\mathbf{b})$ can be interpreted as the value of addressing partial observability, whereas the difference $\hat{v}(\mathbf{b}) - v^*(\mathbf{b})$ can be interpreted as the loss associated with not fully addressing the partial observability.

Bayesian Updating for the Grid. We have noted earlier that for a finite number of grid points, the Bayesian updating of a point does not guarantee the updated point to be in the grid. We have represented the updated belief ($\mathbf{b}'$) as a convex combination of the points in the grid, but we did not specify what the β_ℓ scalars would be.

We need at most m linearly independent vectors to represent any vector in an m -dimensional space. Since our grid, by construction, includes all the extreme points of the belief simplex, which span the entire space, we can always use these points to represent any updated belief $\mathbf{b}' \notin \mathcal{G}$. However, there may be other points in our grid that span the updated belief $\mathbf{b}'$ while, at the same time, yielding better approximate values (better in the sense that is closer to $v^*(\mathbf{b})$). The following linear program would actually find the set of grid points that provide the *best* approximate value while guaranteeing the representation of $\mathbf{b}'$ [19,39]:

$$\begin{aligned} & \text{minimize} && \sum_{\ell=1}^n \hat{v}(\mathbf{b}^\ell) \cdot \beta_\ell \\ & \text{subject to} && \sum_{\ell=1}^n \mathbf{b}^\ell \cdot \beta_\ell = \mathbf{b}', \\ & && \sum_{\ell=1}^n \beta_\ell = 1, \\ & && \beta_\ell \geq 0 \quad \text{for } \ell = 1, \dots, n. \end{aligned}$$

Note that the constraint set guarantees that the updated belief point $\mathbf{b}'$ is spanned by the selected set of grid points. Also note that minimizing the objective function guarantees the best approximate values because of inequality (13). Finally, observe that in order to identify the correct β -weights, this linear programming problem must be solved at every iteration of the solution algorithm (because the values $\hat{v}(\mathbf{b})$ may change from iteration to iteration) for each grid point for each observation and for each action (because each (grid point, observation, action) triplet may yield a different updated belief point). As a result, although each linear programming problem might be solved extremely fast, the number of programs to solve may be enormous.

SUMMARY AND CONCLUSIONS

This article reviews the completely and partially observable Markov decision process models and compares how the optimal value functions of both models relate to each other. Main computational challenges for POMDPs are discussed. The article also derives the grid-based approximation methods for POMDPs, shows how linear programming may be used to derive best possible approximations from these methods, and shows that, at best, grid-based MDPs overestimate true optimal values for POMDPs.

REFLECTED BROWNIAN MOTION

A. B. DIEKER

Georgia Institute of Technology,
Atlanta, Georgia

This article is concerned with a class of d -dimensional Markov processes called *reflected Brownian motions* (RBMs), which are also known as *reflecting Brownian motions* or *regulated Brownian motions*. Attention is restricted from the outset to the case of primary interest in operations research/management science (OR/MS), where the state space of the RBM is the non-negative orthant $S = \mathbf{R}_+^d = \{x \in \mathbf{R}^d : x_1 \geq 0, \dots, x_d \geq 0\}$. The data of the RBM are a d -vector μ , a $d \times d$ covariance matrix Σ , and a $d \times d$ reflection matrix R that satisfies certain restrictions to be specified later.

The behavior of the process can be informally described as follows. In the interior of S , the process behaves like a Brownian motion with covariance matrix Σ and drift μ . Whenever the process touches the boundary ∂S of S and is about to escape from S , it receives an instantaneous push toward the interior of S with a force that is just right in order to keep the process in S . When recording the total push (displacement) received by the process during any time interval through a measure, this measure is singular with respect to Lebesgue measure due to the irregularity of Brownian paths.

The pushing directions on the boundary ∂S of the orthant are determined by the matrix R . Along the relative interior of the $(d-1)$ -dimensional face of points with a vanishing i th coordinate, the pushing direction is constant and is given by the i th column of R . At the intersection of several $(d-1)$ -dimensional faces, any convex combination of pushing directions of the intersecting faces may be used to constrain the process to $\mathbf{R}_+^d$. (This requirement is sometimes relaxed, but it is in force for all the RBMs in this paper.)

Without loss of generality, we follow the convention that the diagonal of R only contains ones.

All vectors in this article are column vectors. For $v \in \mathbf{R}^d$, we write $v \geq 0$ and $v > 0$ if all elements of v are nonnegative and strictly positive, respectively. We also write M' for the transpose of a matrix M . We let $C^d[0, \infty)$ be the set of continuous functions on $[0, \infty)$ with values in $\mathbf{R}^d$, and $C_S^d[0, \infty)$ the subset consisting of $x \in C^d[0, \infty)$ with $x(0) \in S = \mathbf{R}_+^d$.

An account of the developments on the theory of RBM until 1995 is given in the survey by Williams [1]. Since this article aims to discuss the foundations of RBM, some overlap with the material discussed by Williams is inevitable. Even though limited by space restrictions, we have strived to highlight the developments on the theory of RBM since 1995.

CONSTRUCTION OF RBM

This section discusses the mathematical construction of RBM. To successfully construct RBM, one needs conditions on the pushing mechanism to prevent the process from being absorbed on a lower-dimensional face such as the origin. Several approaches can be taken to construct RBM, and we primarily focus on a pathwise construction since it is the closest to the above informal description of RBM. Since we shall see that it is unclear if RBM can always be constructed pathwise, we also discuss methods different from the pathwise construction.

Pathwise Construction

Let a d -dimensional continuous path $x = \{x(t) : t \geq 0\}$ with $x(0) \in S$ be given, from which we aim to construct a path $z = \{z(t) : t \geq 0\}$, which is constrained to $S = \mathbf{R}_+^d$. We interpret x as the “free” path that determines the movements of z while it is in the interior of the state space S .

Definition 1. Let R and $x \in \mathcal{C}_S^d[0, \infty)$ be given. Then $(z, y) \in \mathcal{C}_S^d[0, \infty) \times \mathcal{C}^d[0, \infty)$ is said to be a solution of the *Skorokhod problem* for x if $z(0) = x(0)$ and if we have

- (i) $z(t) = x(t) + Ry(t)$ for all $t \geq 0$,
- (ii) $z(t) \geq 0$ for all $t \geq 0$,
- (iii) for $i = 1, \dots, d$, y_i is nondecreasing and $y(0) = 0$,
- (iv) $\sum_{i=1}^d \int_0^\infty \mathbf{1}_{\{z_i(t) > 0\}} dy_i(t) = 0$.

If (z, y) solves the Skorokhod problem for x , then we write $z \in \Gamma(x)$, and we refer to Γ as the *Skorokhod map*. This map may be multivalued in general.

The interpretation of $Ry(t)$ is the total push that is needed during the time interval $[0, t]$ to keep the path x in $S = \mathbf{R}_+^d$. In conjunction with (i), requirement (iii) ensures that the process can only be pushed in the directions given by the columns of the reflection matrix R . Equation (iv) states that z can only be pushed in an appropriate direction when it is on the boundary of the orthant, so that z moves freely (i.e., without pushing) in the interior of S . Equation (iv) also ensures that the pushing mechanism is “minimal” in the sense that the path cannot be pushed into the interior when it hits the boundary. Only in a few cases can one give “explicit” expressions for y (or equivalently z), a notable example being $d = 1$ and $S = \mathbf{R}_+$ with $R > 0$, in which case $y(t) = -(0 \wedge \inf_{0 \leq s \leq t} x(s)/R)$.

If the reflection matrix R is an M-matrix [2], that is, if it is of the form $I - Q$, where Q is nonnegative with largest absolute eigenvalue less than 1, then there is a unique solution to the Skorokhod problem for any $x \in \mathcal{C}_S^d[0, \infty)$ as shown by Harrison and Reiman [3]. Letting $\{X(t) : t \geq 0\}$ be a d -dimensional Brownian motion starting from $x \in S$ with constant drift $EX(1) - x = \mu$ and constant covariance matrix $\text{Cov}X(1) = \Sigma$, under this assumption on R , the first component of $\Gamma(X)$ becomes a process $Z = \{Z(t) : t \geq 0\}$ starting from x that is confined to the orthant. The resulting process is RBM in S starting from x with reflection matrix R , covariance matrix Σ , and drift μ . However, since the condition on R is not always satisfied in applications, one cannot always construct RBM in this way. The

Harrison–Reiman condition on R has been put in a wider context by Dupuis and Ishii [4] and Dupuis and Ramanan [5].

Two major obstacles for a pathwise construction of RBM are the possible nonexistence and nonuniqueness of the solution to a Skorokhod problem. Clearly, one can only have existence of the solution to a Skorokhod problem with $x(0)$ on the intersection of several $(d - 1)$ -dimensional faces if the process can be pushed onto a higher-dimensional face from there. This condition is known as the *completely-S* condition on the reflection matrix R [6], and immediately translates into the following matrix formulation. The matrix R is *completely-S* if each principal submatrix $\tilde{R}$ of R is an *S*-matrix, where the latter means that there exists some $\tilde{x} \geq 0$ such that $\tilde{R}\tilde{x} > 0$. Bernard and El Kharroubi [7] show that there exists a solution to the Skorokhod problem for any $x \in \mathcal{C}_S^d[0, \infty)$ if and only if R is *completely-S*. According to Williams [1], this result has independently been established by Mandelbaum and Van der Heyden [8]. However, even under the *completely-S* condition, the solution may not be unique since the Skorokhod map is multivalued in general [7,9]. Thus, this existence result cannot be used to construct RBM in the generality that one wishes. A formulation based on the Extended Skorokhod Map, introduced by Ramanan [10], allows one to use a pathwise construction for a class of RBMs that includes some non-SRBMs (semimartingale reflected Brownian motion), but the details fall outside of the current discussion. Lipschitz continuity of the (extended) Skorokhod map has emerged as a critical property for a successful pathwise construction of RBM, see Dupuis and Ramanan [5].

SRBM and Beyond

Unless RBM can be synthesized in a strong sense (pathwise), its construction relies on tools from stochastic calculus such as martingales and their variants, see the section titled “Martingales” in this encyclopedia for background on some of these tools. Semimartingales constitute a particularly convenient class of processes from this point of view, and the semimartingale framework can

be used to construct a process known as the *SRBM* in a “weak” sense.

The key difference between the strong (pathwise) and the weak constructions is that the weak approach constructs a probability space and a stochastic process constrained to the nonnegative orthant, while the strong approach synthesizes sample paths on the given probability space on which a Brownian motion is defined.

A triple $(\Omega, \mathcal{F}, \{\mathcal{F}_t\})$ is called a *filtered space* if Ω is a set, $\mathcal{F}$ is a σ -field of subsets of Ω , and $\{\mathcal{F}_t\}$ is an increasing family of sub- σ -fields of $\mathcal{F}$, that is, a filtration. The following definition is taken from Ref. 11.

Definition 2. An SRBM in the orthant associated with the data (μ, Σ, R) is a continuous, $\{\mathcal{F}_t\}$ -adapted d -dimensional process Z , taking values in $S = \mathbf{R}_+^d$ together with a family of probability measures $\{\mathbb{P}_x : x \in \mathbf{R}_+^d\}$ defined on some filtered space $(\Omega, \mathcal{F}, \{\mathcal{F}_t\})$ for each $x \in \mathbf{R}_+^d$, under $\mathbb{P}_x$, $Z(t) = X(t) + RL(t) \geq 0$ for all $t \geq 0$, where

- (i) X is a d -dimensional Brownian motion with drift vector μ and covariance matrix Σ , $\{X(t) - \mu t : t \geq 0\}$ is a martingale with respect to $\{\mathcal{F}_t\}$, and $X(0) = 0$ $\mathbb{P}_x$ -almost surely,
- (ii) L is an $\{\mathcal{F}_t\}$ -adapted, d -dimensional process such that $L(0) = 0$, L_i is continuous and nondecreasing for $i = 1, \dots, d$, and $\sum_{i=1}^d \int_0^\infty \mathbf{1}_{\{Z_i(s) > 0\}} dL_i(s) = 0$, all $\mathbb{P}_x$ -almost surely.

Relying in part on the results of Reiman and Williams [6], Taylor and Williams [11] show that an SRBM in the nonnegative orthant exists if and only if R is completely- S , and that it is then unique in law and defines a Feller continuous strong Markov process. Note that every SRBM is indeed a semimartingale, since RL is of bounded variation. We refer to Kang and Williams [12] for the construction of SRBM in more general piecewise smooth domains.

One can sometimes construct RBM through a so-called *submartingale problem* [13], but the resulting process may not be a semimartingale. As a consequence, one may need

special tools such as advanced stochastic calculus to study them, see Kang and Ramanan [14]. The submartingale approach itself requires machinery that is outside the scope of this article.

POSITIVE RECURRENCE AND STABILITY

This section discusses positive recurrence of SRBM as defined in Definition 2. Some authors use positive recurrence and stability interchangeably in view of the relation between RBM and stochastic networks. Following Dupuis and Williams [15], we say that an SRBM Z is a *positive recurrent* if for each closed set A in S having positive Lebesgue measure, we have $\mathbf{E}_x[\tau_A] < \infty$, for all $x \in S$, where $\tau_A = \inf\{t \geq 0 : Z(t) \in A\}$ and $\mathbf{E}_x$ denotes expectation under $\mathbb{P}_x$. The next theorem has served as an inspiration for introducing the paradigm of fluid models for studying stochastic networks, see the article titled **Fluid Models of Queueing Networks** in this encyclopedia. Under special conditions on the reflection matrix, this theorem has been refined further by Budhiraja and Dupuis [16].

Theorem 1 [15]. Let Z be a d -dimensional SRBM in $\mathbf{R}_+^d$ associated with the data (μ, Σ, R) for some matrix R with the completely S property.

Assume that the z -component of all solutions of the Skorokhod problem for paths of the form $x(t) = x(0) + \mu t$, for any $x(0) \in \mathbf{R}_+^d$, is attracted to the origin, implying that, for all $\epsilon > 0$, there exists some $T < \infty$ such that $|z(t)| < \epsilon$ for $t \geq T$. Then Z is a positive recurrent and it has a unique stationary distribution.

It has proven challenging to find necessary and sufficient conditions on R and μ for positive recurrence. The conditions

$$R \text{ is nonsingular, } R^{-1}\mu < 0$$

are necessary for positive recurrence [17,18]. They are also sufficient if R satisfies the Harrison–Reiman condition [19], but need not be sufficient otherwise [18]. Hobson

and Rogers [20] formulated necessary and sufficient conditions in the two-dimensional case, see also Ref. 21. The same has recently been achieved for the intrinsically more delicate three-dimensional case, see El Kharroubi *et al.* [22] and Bramson *et al.* [23]. Necessary and sufficient conditions for higher-dimensional SRBMs are currently not known. A by-product of the results in Ref. 23 is that, in three dimensions, the RBM is a positive recurrent if and only if every fluid path is attracted to the origin in the sense of Theorem 1.

THE STATIONARY DISTRIBUTION

This section discusses several aspects of the stationary distribution of SRBM, provided it exists. We focus on analytic formulas for the stationary density, numerical techniques, and large deviations (rough tail asymptotics).

Whenever it exists, the defining property of an invariant measure π is that, for any bounded Borel function ϕ on $\mathbf{R}_+^d$,

$$\int_{x \in S} \mathbf{E}_x[\phi(Z(t))]\pi(\mathrm{d}x) = \int_{x \in S} \phi(x)\pi(\mathrm{d}x).$$

Throughout this section, we assume that we work with a positive recurrent SRBM with a unique stationary distribution and a completely- S reflection matrix. Arguments from Harrison and Williams [19], applied to this more general setting, then show that the SRBM admits a stationary density p_0 with respect to the Lebesgue measure.

The basic adjoint relationship (BAR) [19] is a key tool for studying the stationary distribution for general (S)RBM. It informally gives rise to an elliptic partial differential equation (PDE) with mixed (or oblique) boundary conditions. It remains a challenge to understand the exact role of the nonnegativity constraint in the context of BAR or the associated PDE [17].

Product Forms

Some of the most well-studied stochastic networks admit a so-called product form stationary distribution, see the section titled “Product-Form Queueing Networks” in

this encyclopedia, for examples. Thus, it is natural to investigate when an SRBM in $\mathbf{R}_+^d$ has a stationary density of the form

$$p_0(x) = \prod_{j=1}^d p_j(x_j),$$

where each of the p_j is a density relative to the Lebesgue measure on $[0, \infty)$. Densities of this form are called *product form densities*. The following result has first been established in Ref. 19 under a slightly more restrictive assumption, which can readily be relaxed as noted in Ref. 17.

Theorem 2. *Assume that R is completely- S . A positive recurrent SRBM in $\mathbf{R}_+^d$ associated with data (μ, Σ, R) has a product form stationary density if and only if $-R^{-1}\mu > 0$ and $2\Sigma = R\Lambda + \Lambda R'$, where Λ is a diagonal matrix with the same diagonal entries as Σ . In this case, $p_0(x) = Ce^{-(\eta, x)}$ for $x \in \mathbf{R}_+^d$, where $\eta = -2\Lambda^{-1}R^{-1}\mu$ and $C = \prod_{i=1}^d \eta_i$.*

When the covariance matrix Σ is the identity matrix, the product form condition from Theorem 2 becomes the so-called *skew-symmetry* condition which has been shown to characterize exponential stationary distributions for SRBMs in general polyhedral domains by Harrison and Williams [24,25]. It is an interesting fact that Brownian product-form networks may arise as the heavy-traffic limit of nonproduct form networks, see Harrison and Williams [26]. In that work, the authors show that a product form for SRBM can be interpreted in terms of quasireversibility when R corresponds to a Brownian feedforward (multiclass) network; see the article titled in this encyclopedia for background.

Beyond Product Forms

Little is known regarding the stationary density of SRBM if it fails to be of product form. In some cases, however, the corresponding PDE with mixed boundary conditions can be solved. As a result, the stationary density has been found in seemingly isolated cases, which are currently mostly limited to a two-dimensional setting. The first and, arguably,

“most isolated” case is a specific SRBM given by Harrison [27]. The stationary density in Harrison’s example is found by reformulating the corresponding PDE in polar coordinates and then separating variables.

A relatively wide class of nonproduct-form RBMs is investigated by Knessl and Morrison [28]. They work in the two-dimensional orthant and assume that the covariance matrix is the identity matrix. Much in the spirit of classical results on PDEs with mixed boundary conditions, the resulting stationary densities are expressed as certain integrals and they involve special functions. Similar results have been obtained by Foddy [29] and Harrison *et al.* [30].

Sometimes, the stationary density of a two-dimensional SRBM can be written as a sum of several exponential terms. Foschini [31] and, independently, Karpelevich and Kreinin [32] provide two classes of SRBMs with this property. Through connections with a multidimensional reflection principle for (unconstrained) Brownian motion, Dieker and Moriarty [33] recently unified these results and characterized the class of SRBMs with sum-of-exponential stationary densities in terms of a condition reminiscent of the (product-form) skew-symmetry condition. (Although the results in Ref. 33 are formulated for a wedge, they readily translate into results for the two-dimensional nonnegative orthant through a linear transformation.)

A final isolated case is included in the results of Debicki *et al.* [34], who find the Laplace transform of the stationary distribution of a Brownian motion with a rank-one covariance matrix, which is confined to the orthant. Strictly speaking, owing to the singular covariance matrix, this result falls outside of the RBM framework.

Numerical Techniques

In the absence of analytical expressions, one needs to resort to numerical techniques in order to use RBM for performance analysis. Dai and Harrison [17] introduce a projection method for numerically finding solutions to the BAR, while Chen and Shen [35] investigate a “finite element” method based on earlier work for SRBM in a hypercube [36].

Performance metrics of solutions to the BAR, such as moments of the marginals, can also be found numerically using linear programming; see Schwerer [37] for details.

Large Deviations

The large deviation theory allows one to make powerful statements on the exponential rate at which probabilities converge to zero; see the article titled in this encyclopedia for background. It has been used to study the tail behavior of positive recurrent SRBMs. These tail probabilities indeed decay exponentially under the conditions of Theorem 1, as can be immediately deduced from the fact that SRBM in the nonnegative orthant has a finite moment-generating function in a neighborhood of the origin, that is, there exists some $\varepsilon > 0$ such that for $\theta \in \mathbf{R}^d$ with $\|\theta\| < \varepsilon$,

$$\int_{x \in S} e^{(\theta, x)} \pi(dx) < \infty.$$

This result is due to Budhiraja and Lee [38].

We say that the function $I : \mathbf{R}_+^d \rightarrow [0, \infty]$ is a *rate function* if its level sets $\{x \in \mathbf{R}_+^d : I(x) \leq \alpha\}$ are compact.

Definition 3 [LDP for SRBM]. Suppose an SRBM in $\mathbf{R}_+^d$ has a unique stationary distribution π . We say that it satisfies an LDP with rate function I if for any $A \subset \mathbf{R}_+^d$,

$$\begin{aligned} -\inf_{x \in A^\circ} I(x) &\leq \limsup_{n \rightarrow \infty} \frac{1}{n} \log \pi(nA) \\ &\leq \liminf_{n \rightarrow \infty} \frac{1}{n} \log \pi(nA) \leq -\inf_{x \in \bar{A}} I(x), \end{aligned}$$

where A° and $\bar{A}$ denote the interior and closure of A respectively.

Majewski [39] proves that an LDP holds for a positive recurrent SRBM with either a Harrison–Reiman or a triangular reflection matrix R . Dupuis and Ramanan [40] widen this class and give an alternative “time-reversed” representation of the rate function.

Evaluating the rate function amounts to solving a variational problem over a certain space of absolutely continuous paths. The solution to this problem is currently only

well understood for the two-dimensional non-negative orthant, see Avram *et al.* [41] and Harrison and Hasenbein [21].

Acknowledgments

The author gratefully acknowledges NSF grant EEC-0926308. He is also thankful to Ruth Williams and Kavita Ramanan for valuable suggestions.

REFORMULATION-LINEARIZATION TECHNIQUE FOR MIPs

HANIF D. SHERALI
Grado Department of Industrial
and Systems Engineering,
Virginia Polytechnic Institute
and State University,
Blacksburg, Virginia

Mixed-integer programming (MIP) problems involving binary (0–1) or general discrete decision variables in addition to continuous variables arise in a host of practical applications within the context of production planning and control, network design, location and distribution, and various operational problems in the service sector. Challenging instances of such problems are successfully tackled through a careful initial model construction, followed by a polyhedral analysis to tighten the model representation with respect to its linear programming (LP) relaxation through the addition of suitable valid inequalities, and then utilizing an effective branch-and-cut algorithm. The *reformulation-linearization technique* (RLT) is an automatic model reformulation process that can be used to generate a *hierarchy* of model representations whose continuous relaxations span the spectrum from the ordinary LP relaxation to the convex hull of feasible solutions. The RLT procedure can also be used to derive (facet-defining) valid inequalities for tightening or *lifting* the model representation. Such model augmentation lifting approaches can greatly enhance problem solvability.

To describe the essence of the RLT technique, consider a linear mixed-integer zero–one program, whose feasible region X is defined in terms of n binary variables $x_1, \dots, x_n$ and m (bounded) continuous variables $y_1, \dots, y_m$, respectively comprising the vectors x and y . The RLT process generates a hierarchy of relaxations X_d for the given region X , corresponding to levels $d = 0, 1, \dots, n$, where X_0 is the ordinary continuous or LP relaxation, and where the set

X_d for any $d \in N \equiv \{1, \dots, n\}$ is generated via the following two-step process. The first step is a *reformulation* phase, which utilizes the *bound factors* $x_j \geq 0$ and $(1 - x_j) \geq 0$ for $j \in N$ to construct *bound-factor products of order d* , defined as polynomial terms obtained by selecting some d distinct x -variables, choosing the bound-factor x_j or $(1 - x_j)$ for each selected variable, and then multiplying these bound factors together. Hence, this yields $\binom{n}{d} 2^d$ such bound-factor products.

The defining constraints of X (including the variable bounding restrictions) are multiplied by each of the bound-factor products of order d , where the identity $x_j^2 \equiv x_j$ (i.e., $x_j(1 - x_j) = 0$), $\forall j \in N$, is invoked and used in this multiplication process. This yields a polynomial mixed-integer 0–1 program of degree $\min\{d + 1, n\}$. The second step in the RLT process is a *linearization phase* in which the foregoing polynomial program is linearized by a simple substitution process that replaces each distinct term $\prod_{j \in J} x_j$ with a variable w_J , $\forall J \subseteq N$, and likewise replaces each distinct term $y_k \prod_{j \in J} x_j$ with a variable v_{Jk} , $\forall J \subseteq N, k = 1, \dots, m$. This produces a LP region or polyhedral set X_d in a lifted dimension involving the variable vector (x, y, w, v) . Denoting the projection of X_d onto the original variable space (x, y) as X_{Pd} , Sherali and Adams [1,2] demonstrate that the projections $X_{P0}, X_{P1}, \dots, X_{Pn}$ yield a progression of tighter relaxations leading to the precise convex hull representation, that is

$$\begin{aligned} X_0 &= X_{P0} \supseteq X_{P1} \supseteq X_{P2} \supseteq \dots \supseteq X_{Pn} \\ &= \text{conv}(X), \end{aligned} \quad (1)$$

where $\text{conv}(X)$ denotes the convex hull of X . This result is also shown to hold true when X is defined by polynomial constraints that are linear in y when x is fixed.

References 1 and 2 additionally provide specialized reduced operations that can be used in the reformulation phase in the presence of equality constraints defining X , as well as discuss the use of *constraint*

factors of the type $(\alpha x - \beta)$ based on structural constraints $\alpha x \geq \beta$, in concert with the bound factors, for generating the product terms within the reformulation phase. Also, Refs 3–5 present earlier specialized applications at level $d = 1$ of this novel concept of lifting a model representation through a bound/constraint - factor *multiplication process* followed by a *variable substitution step* to linearize the resulting polynomial program. Boros *et al.* [6] and Lovasz and Shrijver [7] have independently presented similar hierarchies of relaxations, where the latter further incorporates constraints from semidefinite programming. In addition, based on a special case of the RLT process that employs a convexification with respect to a single variable at a time, which is also motivated by disjunctive programming ideas [8,9], Balas *et al.* [10] have developed a *lift-and-project* cutting plane algorithm that is demonstrated to produce encouraging results [11,12].

EXPLOITING SPECIAL STRUCTURES

Sherali *et al.* [13] generalize the RLT process to present a framework that is particularly well suited to exploit frequently occurring special structures such as generalized or variable upper bounds: covering, partitioning, packing constraints, as well as sparsity. Here, suppose the given MIP constrained region X includes the constraints $x \in S \equiv \{x : g_i x \geq g_{0i}, \forall i = 1, \dots, p\}$, where the constraints defining S imply the bounds $0 \leq x_j \leq 1, \forall j \in N$, on the binary variables. Accordingly, define *S-factors of order d* , for any level $d \in \{1, \dots, n\}$, to comprise the collection of products of some d constraint factors $[g_i x - g_{0i}]$, including possible repetitions. Hence, there are $\binom{p+d-1}{d}$ distinct factors of this type at level d . At any given level d , using *S-factors of order d* that are nonnull and nonimplied based on the structure S [13], the generalized RLT process constructs products of these factors with the defining constraints of X while applying the identity $x_j^2 = x_j, \forall j \in N$, at the reformulation phase, and then adopts the variable substitution technique as before in the subsequent

linearization step to generate a hierarchy of relaxations leading to the convex hull representation. Again, specialized reductions are possible in the presence of equality constraints and equality factors [13].

Reference 13 also introduces a novel concept of *conditional logic* whereby the RLT constraints generated at any level can be tightened to improve the relaxation, which would otherwise have been possible only at some higher level in the hierarchy. Here, suppose an RLT constraint is generated by taking the product of some nonnegative polynomial factor $F(x)$ with a defining constraint $\gamma x \geq \gamma_0$ to yield the restriction $\{F(x)[\gamma x - \gamma_0]\}_L \geq 0$, where $\{\cdot\}_L$ denotes the linearization of the polynomial expression $\{\cdot\}$ using the RLT variable substitution process. Now, suppose we can tighten the constraint $\gamma x \geq \gamma_0$ to a stronger restriction $\gamma' x \geq \gamma'_0$ under the condition $F(x) > 0, x \in X$. Then, we can replace the foregoing RLT constraint with the lifted inequality $\{F(x)[\gamma' x - \gamma'_0]\}_L \geq 0$, which is valid whether $F(x) = 0$ or $F(x) > 0$, when $x \in X$. This strategy captures the concepts of strong branching and logical preprocessing, and can be judiciously applied to significantly tighten MIP model representations. Sherali and Driscoll [14] illustrate an application of this concept in the context of lifting the Miller–Tucker–Zemlin formulation of the asymmetric traveling salesman problem.

The hierarchy of higher-dimensional representations produced in this manner markedly strengthens the usual continuous LP relaxation as evidenced in many computational studies on different classes of problems, where even the first-level representation helps design algorithms that significantly dominate existing procedures in the literature [3,5,13,15–18]. The theoretical implications of this hierarchy are noteworthy: the algebraic representation available at level n promotes new methods for identifying and characterizing facets and strong valid linear inequalities in the original variable space, as well as for providing information that directly bridges the gap between discrete and continuous sets. Indeed, as the level n formulation characterizes the convex hull, all valid inequalities in the original variable space

must be obtainable via a suitable projection; thus, such a projection operation serves as an all-encompassing tool for generating valid inequalities. References 19 and 20 provide discussions on generating facets and tight valid inequalities for the Generalized Upper Bound (GUB)-constrained knapsack polytope and the Boolean quadric polytope and Ref. 21 discusses persistency issues for certain constrained and unconstrained pseudo-Boolean programming problems whereby variables that take on 0–1 values at an optimum to an RLT relaxation would persist to take on these same values at an optimum to the original problem. References 22–25 discuss the use of RLT to generate improved model representations for the set-partitioning problem, the quadratic assignment problem, and for 0–1 MIPs subject to various assignment constraints.

GENERAL MIXED-DISCRETE MIPs AND SEMI-INFINITE PROGRAMS

The RLT process has also been extended to address general mixed-discrete problems where the x -variables defining the MIP region X are restricted to take on general discrete values within $S_j \equiv \{\theta_{jk}, k = 1, \dots, k_j\}, \forall j \in N$, as opposed to simply binary values [26,27]. In concept, we can represent such a problem as a 0–1 MIP by adopting the following transformation for each $j = 1, \dots, n$:

$$x_j = \sum_{k=1}^{k_j} \theta_{jk} \lambda_{jk}, \quad \text{where } \sum_{k=1}^{k_j} \lambda_{jk} = 1, \\ \text{and } \lambda_{jk} \in \{0, 1\}, \forall k = 1, \dots, k_j, \quad (2)$$

and then applying the special-structured RLT process [13] discussed in the first section based on the GUB constraints defining the transformation (Eq. 2). In particular, the constraint multiplication process in the RLT reformulation phase recognizes the following identities that are prompted by Equation (2):

$$\{\lambda_{jk_1} \lambda_{jk_2} = 0, \forall k_1 \neq k_2, \forall j\}, \{\lambda_{jk}^2 = \lambda_{jk}, \forall j, k\}, \\ \text{and } \{x_j \lambda_{jk} = \theta_{jk} \lambda_{jk}, \forall j, k\}, \quad (3)$$

and the linearization phase adopts the usual variable substitution process to generate a

hierarchy of relaxations leading to the convex hull representation.

Reference 26 (Chapter 4) exhibits that, under a suitable transformation, the foregoing RLT process can be equivalently conducted directly in the original (x, y) -variable space, without employing the intermediate binary transformation (Eq. 2). The key observation is that the inverse relationship to Equation (2) is given by

$$\lambda_{jk} = \frac{\prod_{p \neq k} (x_j - \theta_{jp})}{\prod_{p \neq k} (\theta_{jk} - \theta_{jp})} \equiv L_{jk}, \text{ say,} \\ \forall k = 1, \dots, k_j, \forall j \in N. \quad (4)$$

Note that $\lambda_{jk} = 1$ if $x_j = \theta_{jk}$, and $\lambda_{jk} = 0$ if $x_j = \theta_{jp}$ for any $p \in \{1, \dots, k_j\} \setminus \{k\}, \forall j \in N$. The polynomial expression (Eq. 4) in x_j , denoted by L_{jk} , is called a *Lagrange interpolating polynomial* (LIP; [28]), and shares the same properties (Eq. 3) as $\lambda_{jk}, \forall j, k$. The reformulation phase of the resulting RLT procedure in the (x, y) -space adopts factors composed of the LIPs L_{jk} to multiply the problem defining constraints; then, applies the following identity akin to Equation (3):

$$x_j L_{jk} = \theta_{jk} L_{jk}, \forall j, k, \quad (5)$$

and finally utilizes a variable substitution process in the linearization phase to replace each distinct product of the x -variables and each distinct product of y_i with the x -variables, $\forall i$, with a new RLT variable, in order to recover the identical hierarchy of relaxations. Reference 27 provides an alternative direct proof of Equation (1) for this latter RLT procedure that uses the LIP factors in the x -space without relying on the intermediate transformation (Eq. 2) by recognizing that the collection of LIPs can be expressed as Kronecker products of matrices given by the inverse of the transpose of Vandermonde matrices. Noting that the Kronecker product of the inverses of a given set of matrices is the inverse of their Kronecker products, a proof of Equation (1) is derived, which thereby directly generalizes the application of RLT for 0–1 MIPs.

Indeed, note that if $S_j = \{0, 1\}$, then L_{jk} reduces to $(1 - x_j)$ and x_j for $k = 1$ and 2 respectively, and Equation (5) produces the familiar identities $x_j(1 - x_j) = 0$ and $x_j^2 = x_j$, respectively, which coincide in this binary case.

Sherali and Adams [29] have shown that Equation (1) holds true even for general mixed-discrete, linear semi-infinite programs. As such, this enables the extension of RLT to bounded 0–1 mixed-integer and mixed-discrete convex programs, where such problems can be equivalently written (implicitly) as semi-infinite programs by using suitable supporting hyperplanes for the region defined by each convex constraint based on the first-order characterization of convexity [30]. Reference 29 presents an inverse transformation mechanism whereby the resulting lifted semi-infinite relaxation at any level can be transformed back into an equivalent finitely constrained convex relaxation defined in terms of the original constraint functions for which the hierarchy (Eq. 1) holds true. In particular, for 0–1 mixed-integer convex programs, this analysis recovers, at the highest level, the convex hull representation derived by Stubbs and Mehrotra [31]. Sherali and Adams [29] also present useful first-level lifted relaxations that can be judiciously applied to solve practical mixed-integer convex programs arising in a wide range of contexts such as robotics, optimal control, finance, and various chemical process and engineering design problems [30,31]. Reference 31 presents encouraging computational results using only a partial first-level RLT relaxation of this type.

SEMIDEFINITE CUTS

Motivated by the semidefinite relaxations of Lovasz and Schrijver [7], Sherali and Fraticelli [32] derive various classes of so-called *semidefinite cuts* that can be used to further tighten RLT relaxations while maintaining linearity, thus facilitating the use of robust, commercial LP software as routines for solving such relaxations within the framework of branch-and-cut algorithms. To

illustrate, consider the first-level RLT relaxation for 0–1 MIPs and let $x_{(1)} \equiv \begin{bmatrix} 1 \\ x \end{bmatrix}$, represent an $(n + 1)$ -dimensional extension of the binary vector x , and consider the matrix $M_1 \equiv [x_{(1)}x_{(1)}^T]_L$, where, as before, $[\cdot]_L$ denotes the linearization of the expression $[\cdot]$ under the RLT variable substitution process, including the application of the identity $x_j^2 = x_j$, $\forall j \in N$ (in the present binary case). Noting that $x_{(1)}x_{(1)}^T$ is symmetric and positive semidefinite (denoted $\succeq 0$), we could require that $M_1 \succeq 0$, that is,

$$\alpha^T M_1 \alpha = [(\alpha^T x_{(1)})^2]_L \geq 0, \forall \alpha \in \mathbb{R}^{n+1}, \|\alpha\| = 1.$$

As such, letting $\bar{M}_1$ represent the evaluation of M_1 at a given solution to an underlying RLT relaxation in the lifted space of the original and new RLT variables, Sherali and Fraticelli [32] present a polynomial-time procedure, having a worst-case complexity $O(n^3)$, which either verifies that $\bar{M}_1 \succeq 0$, or generates a suitable $\bar{\alpha} \in \mathbb{R}^{n+1}$ for which $\bar{\alpha}^T \bar{M}_1 \bar{\alpha} < 0$, thus yielding the semidefinite cut $\bar{\alpha}^T M_1 \bar{\alpha} = [(\bar{\alpha}^T x_{(1)})^2]_L \geq 0$. Furthermore, motivated in part by the moment matrices utilized by Lasserre [33,34] in the context of continuous polynomial programs, Sherali and Desai [35] and Sherali *et al.* [36] extend this concept by replacing $x_{(1)}$ with a vector v that comprises the components of $x_{(1)}$ plus other suitable higher-order monomials, and then invoking $[vv^T]_L \succeq 0$ to generate so-called *v -semidefinite cuts*. Different techniques are described in [35,36] for generating various classes of such v -semidefinite cuts, along with encouraging computational results.

EXTENSION TO CONTINUOUS GLOBAL OPTIMIZATION

The RLT methodology provides a unifying framework for solving not only mixed-discrete polynomial programming problems but also continuous, nonconvex polynomial [37] and factorable [38] optimization problems to global optimality. Here, the *bound factors* $(x_j - \ell_j)$ and $(u_j - x_j)$ are defined with respect to the general bounding restrictions $\ell_j \leq x_j \leq u_j$, for all the variables x_j defining the given nonconvex program, and are used

in concert with the aforementioned constraint factors to generate tight relaxations, which are then embedded within a branch-and-bound algorithm. These relaxations can be further augmented by semidefinite cuts [32,35,36], as well as with other valid inequalities based on grid factors, LIP, and Chebyshev polynomials [38–40]. By utilizing a suitable partitioning process [37,38], such an enumeration process can be induced to converge to a global optimal solution.

References 26 and 41–50 provide additional reading on survey articles and the application of RLT to several special problems (including bilinear, indefinite quadratic, location allocation, and linear complementarity problems) in the domain of both discrete and continuous nonconvex optimization.

REGENERATIVE PROCESSES

CLASSICAL REGENERATIVE PROCESSES

A stochastic process $\{X(t), t \geq 0\}$ is intuitively a regenerative process if it can be split into i.i.d. cycles. That is, we assume that a collection of time points exists, so that between any two consecutive time points in this sequence, (i.e., during a cycle), the process $\{X(t), t \geq 0\}$ has the same probabilistic behavior. There are several proposed definitions that attempt to make this description precise (see Asmussen [1], Çinlar [2], or Thorisson [3]). The classical definition of regenerative processes, which is given below, also demands that the process is independent of its history up to the previous regeneration point, and of the choice of the point itself. This assumption has been relaxed significantly and the notion of regenerative processes that we understand nowadays is wider; we will sketch these ideas in the following sections. This presentation is influenced by many books, which can be found in the references, and draws heavily from Sigman and Wolff [4].

The power of the concept of regenerative processes lies in the existence of a limiting distribution under conditions that are mild and usually easy to verify. For example, in continuous time it is only required that the mean cycle length of the embedded renewal process is finite, that the cycle length distribution is nonlattice, and that the sample paths of the regenerative process satisfy some conditions (e.g., right-continuity with left-hand limits) that are automatic in most examples [Chapter VI] [1].

Classic examples of regenerative processes are ergodic Markov chains and processes. For example, take a Markov chain

or a Markov process with a countable state space E and fix a state i . Assume that the process started at state i . Then every time at which state i is entered is a time of regeneration for the Markov process. As a second example, consider a single-server queueing system with Poisson arrivals and i.i.d. service times. Suppose that we start observing the system at a departure instant, which left behind i customers. Then every time a customer departs leaving behind him i customers is a regeneration epoch and the process describing the queue length after such a time has exactly the same probability law as the one it had at time zero.

We start with the classical definition of a regenerative process.

Definition 1 [Classical Definition].

A regenerative process $\{X(t), t \geq 0\}$ with state space E (endowed with a σ -field $\mathcal{E}$) is a stochastic process on an underlying probability space $(\Omega, \mathcal{F}, \mathbb{P})$ with the following properties: there exists a random variable $R_1 > 0$ such that

- (i) $\{X(t + R_1), t \geq 0\}$ is independent of $\{X(t), t \leq R_1\}$ and R_1 ,
- (ii) $\{X(t + R_1), t \geq 0\}$ is stochastically equivalent to $\{X(t), t \geq 0\}$.

Stochastically equivalent means that the two stochastic processes in (ii) in Definition 1 have the same joint distributions. Because of property (i) in Definition 1, R_1 is a stopping time for $\{X(t), t \geq 0\}$. For a rigorous definition of property (i) in Definition 1, see also Sigman and Wolff [4]. A standard assumption that is often made is that the paths of $X(t)$ are right-continuous with left-hand limits almost surely. This ensures that the sample paths are continuous except possibly on a set of Lebesgue measure 0. We will comment on the necessity of this assumption in the main theorem later on.

The random variable R_1 is called a *regeneration epoch*, and its existence implies the

existence of a sequence of regeneration epochs $\{R_n\}$. This result is carefully proven in Sigman *et al.* [5] and Svertchkov [6]. We say that the process *regenerates* at such epochs. In other words, $\{X(t), t \geq 0\}$ and $\{X(t + R_n), t \geq 0\}$ are stochastically identical, and due to property (i) in Definition 1, $\{X(t + R_n), t \geq 0\}$ is independent of $\{X(t), 0 \leq t \leq R_n\}$. The regeneration epochs generate a renewal process $S_n = R_1 + \dots + R_n$ (see **Definition and Examples of Renewal Processes**), which is called the *embedded renewal process* for the regenerative process $\{X(t), t \geq 0\}$. Moreover, the interval $[S_{n-1}, S_n]$ is called the *nth regenerative cycle*, where we have assumed that $S_0 = 0$. A regenerative process with finite mean cycle length is called *positive recurrent*.

It will sometimes be convenient to allow the process during the first cycle to be different; this simply means that the process during the first cycle may have a distribution that is different from that of subsequent cycles. We call such a process *delayed regenerative*, if the emphasis on the assumptions of the first cycle is needed. From a time-average point of view, the first cycle is not important, provided that it eventually ends. That is, we assume that R_1 is a proper random variable. There are no new tools needed; in handling a delayed regenerative process, we first condition the event or expectation in question on the time R_1 of the first regeneration, and then we use the fact that at R_1 there starts an ordinary regenerative process. Thus, we use the term *regenerative* to cover both cases of delayed or not regenerative processes.

Remark 1. If the distribution of the process during the first special cycle and the length of that cycle are constructed in a particular way, then we can construct a stationary regenerative process, which implies that the distribution of $\{X(t), t \geq 0\}$ is independent of t for all t ; see Wolff [7] for a construction.

An important fact that follows directly from the classical definition is that functions of regenerative processes are also themselves regenerative.

Proposition 1 [Inheritance of Regenerations]. *If $\{X(t), t \geq 0\}$ with state space E is a regenerative process with regeneration epochs R_n , then $\{f(X(t)), t \geq 0\}$ is also a regenerative process (with some state space E') with the same regeneration epochs for any $f : E \rightarrow E'$.*

For instance, take $\{X(t), t \geq 0\}$ to be a regenerative process and consider the function $\hat{X}(t) = \mathbf{1}(X(t) \in B)$ for some set B . Since $X(t)$ is regenerative, then so is $\hat{X}(t)$, which can help one compute the distribution of one regenerative process as the expectation of another, that is, $\mathbb{P}(X(t) \in B) = \mathbb{E}[\hat{X}(t)]$. This proposition illustrates a more general observation that the embedded renewal times of a regenerative process need not be stopping times with respect to the evolution of $X(t)$. Observe that in contrast a function of a Markov process is usually not a Markov process itself. Nevertheless, it remains regenerative if the Markov process is so.

Other than computing the limiting distribution of one regenerative process via another, one could use the inheritance of regenerations to add a cost or reward function to the process. Namely, if we assume that the system earns rewards (that may be negative) at a rate $c(x)$ whenever it is in state x , then the total reward up to time t is given by $\int_0^t c(X(y)) dy$, where $\{c(X(y)), y \geq 0\}$ is a regenerative process. For finite mean cycle lengths, the time average of $c(x)$ defined to be equal to $\lim_{t \rightarrow \infty} \int_0^t c(X(y)) dy / t$ can be found by the renewal-reward theorem (see Theorem 1 in **Renewal Processes with Costs and Rewards**). In particular, it can be shown with standard methods that

$$\lim_{t \rightarrow \infty} \int_0^t c(X(y)) dy / t = \int_{-\infty}^{\infty} c(y) dF(y),$$

where $F(x)$ is the limiting distribution of the regenerative process $\{X(t), t \geq 0\}$, which is given below in Theorem 1 by choosing $(-\infty, x]$ for the set B appearing in Equation (1).

The primary use of the key renewal theorem (see **Limit Theorems for Renewal Processes**) is in characterizing the limiting behavior of regenerative processes. Renewal

theory is the main tool for studying regenerative processes in the absence of further properties. Conversely, it is this applicability to regenerative processes, which makes renewal theory one of the most important tools in elementary probability theory. The time average properties of regenerative processes are straightforward consequences of the renewal-reward theorem (which is based on the strong law of large numbers). This follows from the fact that the cycles, and the process during each cycle, are i.i.d. We proceed with the main theorem in this section, which gives the limiting distribution of a regenerative process.

Theorem 1 [Limiting Behavior of Regenerative Processes]. *Suppose that the process $\{X(t), t \geq 0\}$ is regenerative with regeneration epochs with finite mean, that is, $\mathbb{E}[R_1] < \infty$. We then have*

- (a) *The limiting distribution of the regenerative process in the time average sense exists; that is, the limit $\lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t \mathbf{1}(X(s) \in B) ds$ exists for all measurable sets B , $B \in \mathcal{E}$, where $\mathbf{1}(\cdot)$ is the indicator function. For $B = (-\infty, x]$ we denote it by $F(x)$. Moreover, if we denote by X_∞ a generic random variable with this limiting distribution, we have that*

$$\begin{aligned} \mathbb{P}(X_\infty \in B) &= \frac{1}{\mathbb{E}[R_1]} \\ &\times \mathbb{E} \left[\int_0^{R_1} \mathbf{1}(X(s) \in B) ds \right], \quad B \in \mathcal{E}. \end{aligned} \quad (1)$$

- (b) *If the state space E is a complete separable metric space and the process $\{X(t), t \geq 0\}$ has right-continuous paths, then in case the cycle length distribution is nonlattice, we have that $\mathbb{P}(X(t) \in B)$ converges weakly to $\mathbb{P}(X_\infty \in B)$. Moreover, for a measurable function $f : E \rightarrow \mathbb{R}$ we have that*

$$\begin{aligned} &\lim_{t \rightarrow \infty} \mathbb{E}[f(X(t))] \\ &= \frac{1}{\mathbb{E}[R_1]} \mathbb{E} \left[\int_0^{R_1} f(X(s)) ds \right], \end{aligned} \quad (2)$$

which for the special case where f is the indicator function, yields that $\lim_{t \rightarrow \infty} \mathbb{P}(X(t) \in B) = \mathbb{P}(X_\infty \in B)$ is equal to the right-hand side of Equation (1).

- (c) *If the cycle length distribution is spread out, then $\mathbb{P}(X(t) \in B)$ converges to $\mathbb{P}(X_\infty \in B)$ in total variation (i.e., the convergence is uniform over all Borel sets B).*

For a regenerative process in discrete time, the above theorem holds in case the cycle length is aperiodic. If it is periodic with period d , the above limit holds if $t = nd$ and $n \rightarrow \infty$ [1,8]. Serfozo [9] derives Equation (2) without the assumptions under (b) in Theorem 1, but with the assumptions that the cycle length distribution is nonlattice and that for $M = \sup\{|f(X(t))| : t \leq R_1\}$, M and MR_1 have finite means.

From this theorem we see that the limiting distribution for a regenerative process, $\mathbb{P}(X_\infty \in B)$, is equal to the expected time that the process spent in B over the expected inter-renewal time. Evidently, if the embedded renewal process is recurrent but with $\mathbb{E}[R_1] = \infty$, then we have that $\mathbb{P}(X_\infty \in B) = 0$. One could use the above theorem to derive the Laplace–Stieltjes transform of the limiting distribution of $\{X(t), t \geq 0\}$ by the appropriate choice of the function f appearing in (b) in Theorem 1.

This theorem is also true, with slight modifications, for delayed regenerative processes. We, namely, have to integrate over a proper regenerative cycle, say $[S_1, S_2)$, rather than the first special cycle.

Example 1 [Age Process]. Evidently, the process Z_t giving the time from t until the next renewal in a renewal process is a regenerative process.

Example 2 [GI/GI/1 Queue]. Let $\{X(t), t \geq 0\}$ be the number of customers in a GI/GI/1 queue and let S_n be the n th time when a customer enters an empty system. Provided that the occupation rate of the system is less than 1 (i.e., that the mean service time is less than the mean interarrival time), the mean cycle length is finite. If the

process starts with a customer entering an empty system at time 0, then $\{X(t), t \geq 0\}$ is a regenerative process; otherwise it is a delayed regenerative process. The state space of this regenerative process is given by $\{0, 1, 2, \dots\}$. Then, under the assumptions of the theorem above

$$\begin{aligned} \lim_{t \rightarrow \infty} \mathbb{P}(X(t) = j) &= \frac{\mathbb{E}[\text{time in state } j \text{ during a cycle}]}{\mathbb{E}[\text{time of a cycle}]} \\ &= \lim_{t \rightarrow \infty} \frac{\mathbb{E}[\text{time in } j \text{ during } (0, t)]}{t}. \end{aligned}$$

That is, $\lim_{t \rightarrow \infty} \mathbb{P}(X(t) = j)$ is not only the probability that the regenerative process is in state j in steady state (i.e., the probability that there are j customers in the system in steady state), but also the long-run proportion of time that the process was in state j . To prove this result, one simply needs to assume that a reward is earned at rate 1 each time the process is in state j , which generated a renewal-reward process and the equality is then a consequence of the renewal-reward theorem (or of Theorem 1 above, for a particular choice of f).

Example 3 [I.i.d. Random Variables].

Any independent and identically distributed sequence of random variables is a regenerative process. The embedded renewal process is simply the counting process of the sequence $(S_n = n)$. If these random variables are continuous, we observe that the process returns to a fixed state with probability zero, and thus, the regeneration epochs cannot be defined as returns to any particular fixed state; contrast this with the fact that in the GI/GI/1 queue example above, returns to the fixed state “the number of customers in the queue is zero” were chosen to be the regenerative epochs.

As mentioned earlier, one can find several examples of regenerative processes in Markov chains and Markov processes.

Remark 2. There is a version of the central limit theorem for regenerative processes that can be used to construct confidence intervals

when simulating regenerative processes; see Sigman and Wolff [4] and Wolff [7] for details.

ONE-DEPENDENT REGENERATIVE PROCESSES

The definition of regenerative processes has been extended to allow for one-dependent cycles, which connects regenerative processes to Harris-recurrent Markov chains. Many-server queues formed the main motivation to extend the classical notion of regeneration to this definition [4]. Previously, for the GI/GI/1 queue we had taken the times when the system empties as the regeneration epochs. Suppose now you have a GI/GI/2 queue, which is stable, that is, the offered load to the system per server is less than 1. Take a completely deterministic system where service takes 1.5 time units and customers arrive every 1 time unit. Let the first arrival occur at time 0. Then we observe that this system never empties. Thus, we are not able to define the same regeneration epochs (i.e., an empty system) as for the single-server queue. The question is now if one should infer that the queue length process is not regenerative.

The definition of regenerative processes we have used so far demands that $\{X(t + R_1), t \geq 0\}$ is independent both of R_1 and of $\{X(t), t \leq R_1\}$ (see Definition 1). A more general definition is given in Asmussen [1] where the requirement now is that $\{X(t + R_1), t \geq 0\}$ is independent only of R_1 but not necessarily of $\{X(t), t \leq R_1\}$. Under both definitions, $\{X(t + R_1), t \geq 0\}$ is stochastically equivalent to $\{X(t), t \geq 0\}$. As a result, the embedded renewal process has i.i.d. cycles, but the regenerative process might be dependent. Asmussen [1] shows that under this definition, the process is *one-dependent*, namely, the process during adjacent cycles is dependent, but during nonadjacent cycles it is independent (see also [10]). If a process is regenerative under Definition 1, then it is naturally also so under this definition, while evidently, the converse is not true.

Definition 2 [One-Dependent Definition]. A regenerative process $\{X(t), t \geq 0\}$ with state space E (endowed with a σ -field $\mathcal{E}$) is a stochastic process on an underlying probability space $(\Omega, \mathcal{F}, \mathbb{P})$ with the following properties: there exists a random variable $R_1 > 0$ such that

- (i) $\{X(t + R_1), t \geq 0\}$ is independent of R_1
- (ii) $\{X(t + R_1), t \geq 0\}$ is stochastically equivalent to $\{X(t), t \geq 0\}$.

Since the cycle lengths R_n are still i.i.d., they generate an embedded renewal process. Thus, Equation (2) still holds; the regenerative process converges in distribution to its limit (and also in total variation). This definition can be used to characterize Harris-recurrent Markov chains, as a Markov chain is positive Harris recurrent if and only if it is regenerative under the one-dependent definition and ergodic for every initial state x , with the distribution of the process during a cycle (possibly excluding the first one for the delayed case) not depending on the initial state x [4,11]. We usually think of queues as continuous-time processes, but we can embed discrete-time processes in them, as for example, instances when a customer arrives. Embedded processes for several queueing models turn out to be regenerative under the one-dependent definition, and with finite mean cycle lengths [12,13]. Returning to the GI/GI/2 example mentioned above, it has been shown [14] that the vector giving the workload for each server is a Harris ergodic Markov chain and thus it has a regenerative structure [7,13].

FURTHER READING

The interested reader should start with the comprehensive and in-depth review of regenerative processes by Sigman and Wolff [4]; several important references on the topic can be found there—we present only a few of them. Smith [15,16] constructs a regenerative process under the classical definition using random tours; see also [17]. As this

topic is an integral part of stochastic processes, most books on stochastic processes have some treatment of (classical) regenerative processes [2,8,9,17–19]. References on how to simulate a stationary version of a regenerative process have been omitted; few of them can be found in the sources cited here.

The notion of regeneration has been extended to even more general definitions. Rather than demanding that the regenerative epochs R_n form an i.i.d. sequence (cf. property (i) in Definition 2), one can extend the notion of the dependence of $\{X(t)\}$ on the process in adjacent cycles, to one-dependence of the cycle lengths themselves. In Sigman [11] it is shown that these processes are related to *continuous-time* Harris-recurrent Markov processes; (compare this to what has been mentioned in the previous section that Definition 2 is related to Harris ergodic chains, i.e., in discrete time). Further examples of this extended notion of one-dependence of regenerative processes include the superposition of two independent renewal processes where at least one of them has a spread-out cycle length distribution.

Another way of describing the regenerative structure for a recursive sequence as this was given under Definition 2 is by the *renewing events* or *renovation method* [20,21]. This amounts to first *algebraically* describing the independence of the past property rather than doing so in a probabilistic fashion; see Sigman and Wolff [4] for an example.

A further extension is the notion of *synchronous processes*; a stochastic process $\{X(t), t \geq 0\}$ is called *synchronous* if there exists a random variable $R_1 > 0$ such that $\{X(t + R_1), t \geq 0\}$ is stochastically equivalent to $\{X(t), t \geq 0\}$, possibly by enlarging the probability space, if necessary. That is, we no longer require property (i) in Definition 2 [22–24].

Other notions of regenerative processes worth mentioning are those of Kingman [25,26] in which the kind of regenerative structure found in discrete-state Markov processes is generalized by allowing any of the continuum of times during the visit to a recurrent state to serve as a regeneration epoch and that of Thorisson [3], who introduces the notion of a time-inhomogeneous

regenerative process, which can apply, for example, to an inhomogeneous Markov chain with a recurrent state.

The list of references here is by no means exhaustive, but should serve only as a starting point.

REINFORCEMENT LEARNING ALGORITHMS FOR MDPs

CSABA SZEPESVÁRI
Department of Computing Science,
University of Alberta, Edmonton,
Alberta, Canada

OVERVIEW

Reinforcement learning (RL) refers to both a learning problem and a subfield of machine learning. As a learning problem it refers to learning to control a system so as to maximize some numerical value which represents a long-term objective. A typical setting where RL operates is shown in Fig. 1: A controller receives the controlled system's state and a reward associated with the last state transition. It then calculates an action which is sent back to the system. In response, the system makes a transition to a new state and the cycle is repeated. The problem is to learn a way of controlling the system so as to maximize the total reward. The learning problems differ in the details of how the data is collected and how performance is measured.

In this article we assume that the system that we wish to control is stochastic. Further, we assume that the measurements available on the system's state are detailed enough so that the controller can avoid reasoning about how to collect information about the state. Problems with these characteristics are best described in the framework of Markovian decision processes (MDPs). The standard approach to "solve" MDPs is to use dynamic programming, which transforms the problem of finding a good controller into the problem of finding a good value function. However, apart from the simplest case when the MDP has very few states and actions, dynamic programming is infeasible. The RL algorithms discussed here can be thought of as a way of turning the infeasible dynamic programming methods into practical algorithms so that they can be applied to large-scale problems.

There are two key ideas that allow RL algorithms to achieve this goal. The first is to use samples to compactly represent the dynamics of the control problem. This is important for two reasons: First, it allows one to deal with learning scenarios when the dynamics is unknown. Second, even if the dynamics is available, exact reasoning might be intractable on its own. The second key idea behind RL algorithms is to use powerful function approximation methods to compactly represent value functions. The significance of this is that it makes dealing with large, high-dimensional state- and/or action-spaces possible. What is more, the two ideas fit nicely together: Samples may be focused on a small subset of the spaces they belong to, which clever function approximation techniques might exploit. It is the understanding of the interplay between dynamic programming, samples and function approximation that is at the heart of designing, analyzing and applying RL algorithms.

The interested reader is invited to learn more about RL by consulting the rich literature. The first survey that appeared on RL is due to Kaelbling *et al.* [1], which was followed by the publication of the books by Bertsekas and Tsitsiklis [2] and Sutton and Barto [3]. The book by Bertsekas and Tsitsiklis [2] discusses the theoretical foundations, while the book by Sutton and Barto [3] focuses on presenting the core ideas in an accessible manner. More recent books that are devoted in part or in whole to the subject include those by Gosavi [4], Cao [5], Bertsekas [6,7], Powell [8], Chang *et al.* [9], Busoniu *et al.* [10] and Szepesvári [11]. On-line, periodically updated summaries are provided by Bertsekas [12] and Szepesvári [13].

The rest of this article is organized according to Fig. 2. After introducing our notation (see the section titled "Preliminaries"), we consider value prediction problems, describe TD(λ) and its recent improved versions, along with least-squares methods. In the section titled "Control", we discuss a few algorithms for control, most notably Q-learning and

Figure 1. The basic reinforcement learning scenario.

Figure 2. Types of reinforcement problems and approaches. The article gives examples of algorithms for all approaches except for (direct) policy search.

fitted Q-iteration, which can be thought of as implementing value iteration. This is followed by a description of an actor-critic algorithm, which can be thought of as implementing policy iteration. Owing to the lack of space, the discussion of (direct) policy search methods is not included.

PRELIMINARIES

We assume that the reader is familiar with MDPs. Accordingly, the sole purpose of this section is to introduce the notation used in the rest of the article.

We consider controlled stochastic process with Markovian dynamics:

$$\begin{aligned} X_{t+1} &= f_1(X_t, A_t, D_{t+1}), \\ R_{t+1} &= f_2(X_t, A_t, D_{t+1}), \quad t = 0, 1, \dots \end{aligned} \quad (1)$$

Here, $X_t \in \mathcal{X}$ is the state of the system at time t , $A_t \in \mathcal{A}$ is the action taken by the controller after X_t was observed, D_{t+1} is a disturbance

term (taking values in some Euclidean space), and $R_{t+1} \in \mathbb{R}$ is the reward received.¹ The disturbance sequence $(D_t; t \geq 1)$ is a sequence of independent, identically distributed (i.i.d.) random variables. The goal of the controller is to maximize the expected total discounted reward, or *expected return*, irrespective of the initial state

$$\mathbb{E} \left[\sum_{t=0}^{\infty} \gamma^t R_{t+1} \mid X_0 = x \right] \rightarrow \max!, \quad x \in \mathcal{X}.$$

Here, $0 < \gamma < 1$ is the so-called *discount factor*. The process $((X_t, A_t, R_{t+1}); t \geq 0)$ is called a *Markov Decision Process*.² In the applications, f is usually a smooth function of its arguments.

Equation (1) specifies an MDP in the so-called state-space form. An equivalent definition can be given in terms of a transition probability kernel $\mathcal{P}_0$ which assigns to each state-action pair $(x, a) \in \mathcal{X} \times \mathcal{A}$ a probability measure over $\mathcal{X} \times \mathbb{R}$. Denoting the latter by $\mathcal{P}_0(\cdot \mid x, a)$, the connection between the two formalisms is given by

$$\mathcal{P}_0(U \mid x, a) = \mathbb{P}(f(x, a, D) \in U),$$

where $f(x, a, d) = (f_1(x, a, d), f_2(x, a, d))$ and D is a random variable whose distribution is the same as that of D_t .

For simplicity, consider the case when the action set $\mathcal{A}$ is countable. A general policy determines the actions chosen as a function of history. The *value* of state x under a policy π is the expected return given that the policy is started in state x , while the *action value* of a state-action pair (x, a) is the expected

¹Here, we assumed that all actions are admissible in all states. Sometimes it is necessary to restrict the set of actions admissible to a subset of the actions in a state-dependent manner. The results and algorithms presented here extend to this case essentially without any change.

²The algorithms described below have been extended to other than the expected total discounted reward, such as the expected total reward (i.e., no discounting) or the average reward criteria. The discounted criterion is selected because it allows a simpler presentation of the main ideas.

return given that the process is started from state x , the first action is a after which the policy π is followed. The value of state x under policy π is denoted by $V^\pi(x)$, while the action value of the pair (x, a) under policy π is denoted by $Q^\pi(x, a)$.

The *optimal value* of a state is the value of the best possible expected return that can be obtained from that state. It is denoted by $V^*(x)$: $V^*(x) = \sup_\pi V^\pi(x)$. Similarly, the optimal value of a state-action pair is $Q^*(x, a) = \sup_\pi Q^\pi(x, a)$. A policy is called *optimal* if $V^\pi(x) = V^*(x)$ holds for all states $x \in \mathcal{X}$. A policy is called *stationary* if the actions selected at any step depend only on the last state. A stationary policy can thus be specified by specifying a distribution $\pi(\cdot|x)$ over actions for each state of the state space. Under mild regularity assumptions (e.g., assuming that $\sup_{x,a} \mathbb{E}[f_2(x, a, D)] < +\infty$ and that $\mathcal{A}$ is finite), an optimal stationary policy exists and in fact any stationary policy π that satisfies $\sum_{a \in \mathcal{A}} \pi(a|x) Q^*(x, a) = \max_{a \in \mathcal{A}} Q^*(x, a)$ for every state $x \in \mathcal{X}$ is optimal. Given some function $Q : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}$, a maximizer of $Q(x, \cdot)$ is called a *greedy action* with respect to (w.r.t.) Q . A policy π is greedy w.r.t. Q if it is greedy w.r.t. Q in every state $x \in \mathcal{X}$.

Dynamic Programming Algorithms

Value- and *policy iteration* are the standard algorithms of dynamic programming to find optimal (or near-optimal) policies in MDPs.

Value iteration generates a sequence of value functions $V_{k+1} = T_1^* V_k$, $k \geq 0$, where V_0 is arbitrary. Thanks to Banach's fixed-point theorem, $(V_k; k \geq 0)$ converges to V^* at a geometric rate. Here, the operator $T_1^* : B(\mathcal{X}) \rightarrow B(\mathcal{X})$ is defined by $T_1^* V(x) = \sup_{a \in \mathcal{A}} \mathbb{E} [f_2(x, a, D) + \gamma V(f_1(x, a, D))]$, where $B(\mathcal{X})$ is the set of bounded functions over $\mathcal{X}$. The operator T_1^* is shown to be a γ -contraction w.r.t. the supremum norm.

Value iteration can also be used in conjunction with action-value functions, in which case it takes the form $Q_{k+1} = T_2^* Q_k$, $k \geq 0$, which again converges to Q^* at a geometric rate. Here, the operator $T_2^* : B(\mathcal{X} \times \mathcal{A}) \rightarrow B(\mathcal{X} \times \mathcal{A})$ is defined by $T_2^* Q(x, a) = \mathbb{E} [f_2(x, a, D) + \gamma \sup_{a' \in \mathcal{A}} Q(f_1(x, a, D), a')]$ and is again a contraction. Both T_1^* and T_2^* are called *Bellman-optimality operators*.

It can be shown that once V_k (or Q_k) is close to V^* (respectively, Q^*), a policy that is greedy with respect to V_k (respectively, Q_k) will be close to optimal. In particular, the following bound is known to hold [[14], Corollary 2]:

$$V^\pi(x) \geq V^*(x) - \frac{2}{1-\gamma} \|Q - Q^*\|_\infty, \quad x \in \mathcal{X}. \quad (2)$$

Here, π is any policy that is greedy policy w.r.t. Q , and Q is an arbitrary real-valued function over the state-action space.

Let us now consider *policy iteration*. Fix an arbitrary initial policy π_0 . At iteration $k > 0$, compute the action-value function underlying π_k (this is called the *policy evaluation step*). Next, given Q^{π_k} , define π_{k+1} as a policy that is greedy with respect to Q^{π_k} (this is called the *policy improvement step*). The steps when π_{k+1} is computed from π_k define an update of *policy iteration*.

After k iterations, policy iteration gives a policy not worse than the policy that is greedy w.r.t. to the value function computed using k iterations of value iteration provided that the two procedures were started with the same initial value function. However, the computational cost of a single update in policy iteration is much higher (because of the policy evaluation step) than that of one update in value iteration.

For more information on MDPs consult Bertsekas and Shreve [15] or Puterman [16].

VALUE PREDICTION PROBLEMS

Value prediction is the problem of predicting the value of states (or state-action pairs) under a stationary policy π . The data is given in the form of a series of transitions, $\mathcal{D} = ((X_t, R_{t+1}, Y_{t+1}); t = 0, 1, \dots)$, where $(Y_{t+1}, R_{t+1}) = f(X_t, A_t, D_{t+1})$ and $A_t \sim \pi(\cdot|X_t)$. The goal is to learn a predictor for $V^\pi(\cdot)$. Here, the process generating X_t is either left unspecified, or $Y_{t+1} = X_{t+1}$; that is, the data is given in the form of a single trajectory. When X_t has a limiting distribution that corresponds to the stationary distribution of π (which is assumed to exist), we talk

about an *on-policy setting*, otherwise we talk about an *off-policy setting*. The off-policy setting comes up, for example, when one uses a simulator and time-to-time the states X_t are reset to specific states of interest. The on-policy setting comes up when such “resetting” of the state is not available, as in the case when learning happens while interacting with a real system.

TD(λ) with Linear Function Approximation

When the state space is large, it is infeasible to keep an estimate of the values of all states (the array storing the values may not fit into the memory). One way to get around this problem is to use a function approximation method, a special case of which is when a *linear function approximation method* is used. Such a method approximates the value at a state x by first calculating some *features* $\varphi(x) \in \mathbb{R}^d$ and then linearly combining these with some weights θ :

$$V^\pi(x) \approx \theta^\top \varphi(x).$$

The features are usually designed (picked) by hand so that they capture the properties of the state that the user thinks are important for predicting the values. The design of the features usually needs prior knowledge, though one can always resort to some general constructions, like tile coding or radial basis functions. Once the features are selected we are left with finding the weights so that V^π is well approximated. This is the job of the learning algorithms. Although it might seem a lot to ask the user to select the features, that the weights are tuned automatically is a major achievement whose significance should not be underestimated.

Algorithm 1. The function implementing the TD(λ) algorithm with linear function approximation. This function must be called after each transition.

function TDLambdaLinFApp(X, R, Y, θ, z)

Input: X is the last state, Y is the next state, R is the immediate reward associated with this transition, $\theta \in \mathbb{R}^d$ is the parameter vector of the linear function approximation, $z \in \mathbb{R}^d$ is the vector of eligibility traces

1: $\delta \leftarrow R + \gamma \cdot \theta^\top \varphi[Y] - \theta^\top \varphi[X]$

2: $z \leftarrow \varphi[X] + \gamma \cdot \lambda \cdot z$

3: $\theta \leftarrow \theta + \alpha \cdot \delta \cdot z$

4: **return**(θ, z)

The TD(λ) algorithm of Sutton [17] (see also Sutton [18]) is one widely used and successful method that allows one to tune the weights in an incremental manner. The pseudocode of the update rule for TD(λ) is shown as Algorithm 1. The routine shown must be called for each sampled transition. The name of the algorithm is derived from the abbreviation of temporal differences and it comes from line 1, where δ , which can be thought of as a temporal difference error is computed. In addition to the data underlying a transition, the method expects the current weights θ , and the current *eligibility traces* z as inputs. Here, both θ and z are d -dimensional vectors. The routine then returns the updated values of these vectors.

The tuning parameters of TD(λ) are $\lambda \in [0, 1]$ and the step-size $\alpha \geq 0$. In practice, one often uses d step-sizes, one for each component of the weight vector. The step-sizes should be inversely proportional to the expected magnitudes of the respective feature components. The λ parameter determines the amount of “bootstrapping.” When the dynamics is well preserved by the feature-extraction method (e.g., $\varphi(Y_{t+1})$ and the reward can be well predicted given $\varphi(X_t)$ and the action), a small value of λ is appropriate (and the algorithm can be thought of as implementing an incremental form of value iteration). In the opposite case, $\lambda \approx 1$ is more appropriate and the algorithm can be thought of as implementing a Monte Carlo algorithm. In general, increasing λ increases the variance, but decreases the bias. The best value of λ is problem dependent and is usually found by trial-and-error in small-scale experiments before the algorithm is run on a larger chunk of data. When $\lambda = 0$, the algorithm is also called TD(0), while it is also called TD(1) when $\lambda = 1$.

Almost sure convergence of the weights is guaranteed provided that (i) the stochastic process $(X_t; t \geq 0)$ is an ergodic Markov process whose stationary distribution μ is the same as the stationary distribution of the policy π ; and (ii) the step-size sequence satisfies the so-called Robbins–Monro (RM) conditions [[2], p. 222, Section 5.3.7; [19]].³ When the first condition is not met, that is, under off-policy sampling, convergence is no longer guaranteed, but in fact the parameters may diverge [[2], Example 6.7, p. 307]. This is true for linear function approximation when the distributions of $(X_t; t \geq 0)$ do not match the stationary distribution of π . The TD(λ) method has a version that is suitable for tuning the parameters of nonlinear function approximation methods, such as neural networks. However, this standard version might diverge [[2], Example 6.6, p. 292]. For further examples of instability, see Baird [20] and Boyan and Moore [21].

Gradient Temporal Difference Learning.

In this section, we present two algorithms, which overcome the instability of TD(λ) while retaining its incremental nature and the computational efficiency of the updates.

The key is to introduce an objective function and derive a gradient method from it. For simplicity, we consider the case when $\lambda = 0$. Define the objective function

$$J(\theta) = \mathbb{E} [\delta_{t+1}(\theta) \varphi_t]^\top \mathbb{E} [\varphi_t \varphi_t^\top]^{-1} \mathbb{E} [\delta_{t+1}(\theta) \varphi_t], \quad (3)$$

where

$$\begin{aligned} \delta_{t+1}(\theta) &= R_{t+1} + \gamma V_\theta(Y_{t+1}) - V_\theta(X_t) \\ &= R_{t+1} + \gamma \theta^\top \varphi'_{t+1} - \theta^\top \varphi_t, \\ \varphi_t &= \varphi(X_t), \\ \varphi'_{t+1} &= \varphi(Y_{t+1}). \end{aligned} \quad (4)$$

³The RM conditions state the following: if $(\alpha_t; t \geq 0)$ are the step-sizes used in time step t , then $\sum_{t=0}^{\infty} \alpha_t = \infty$ and $\sum_{t=0}^{\infty} \alpha_t^2 < \infty$. They are satisfied by, for example, $\alpha_t = 1/t$. In practice, people often use small constant step-sizes or adaptive step-size selection methods.

Here, for simplicity we assumed that $(X_t; t \geq 0)$ is a stationary process, so the expectation in Equation (3) is well defined.

When TD(0) converges, it converges to a unique vector θ^* that satisfies

$$\mathbb{E} [\delta_{t+1}(\theta^*) \varphi_t] = 0. \quad (5)$$

In this case, the minimizer of J will coincide with θ^* . Therefore, it suffices to design an algorithm to minimize J . Accordingly, from now on let us redefine θ^* as the minimizer of J (for simplicity, assume that the minimizer is unique).

Taking the gradient of J , we get

$$\nabla_\theta J(\theta) = -2 \mathbb{E} [(\varphi_t - \gamma \varphi'_{t+1}) \varphi_t^\top] w(\theta), \quad (6)$$

where

$$w(\theta) = \mathbb{E} [\varphi_t \varphi_t^\top]^{-1} \mathbb{E} [\delta_{t+1}(\theta) \varphi_t].$$

Let us introduce two sets of weights: θ_t to approximate θ_* and w_t to approximate $w(\theta_*)$. In GTD2 (“gradient temporal difference learning, version 2”), the update of θ_t is chosen to follow the negative stochastic gradient of J based on Equation (6) assuming that $w_t \approx w(\theta_t)$, while the update of w_t is chosen so that for any fixed θ , w_t would converge almost surely to $w(\theta)$. The pseudocode of the resulting update, which Sutton *et al.* [22] called the GTD2 update, is shown as Algorithm 2. This algorithm needs two sets of step-sizes (α, β) .

Sutton *et al.* [22] have shown that (under the standard RM conditions on the step-sizes and some mild regularity conditions) the weight-sequence (θ_t) updated with GTD2 converges to the minimizer of $J(\theta)$ almost surely. However, unlike in the case of TD(0), convergence is guaranteed independently of what the distribution of $(X_t; t \geq 0)$ is. At the same time, the update of GTD2 costs only twice as much as that of TD(0).

One can arrive at another gradient method if the gradient of J is written as

$$\begin{aligned} \nabla_\theta J(\theta) &= -2 \left(\mathbb{E} [\delta_{t+1}(\theta) \varphi_t] - \right. \\ &\quad \left. \gamma \mathbb{E} [\varphi'_{t+1} \varphi_t^\top] w(\theta) \right). \end{aligned}$$

This suggests replacing the update in line 5 of GTD2 by

$$\theta \leftarrow \theta + \alpha \cdot (\delta \cdot f - \gamma \cdot a \cdot f'),$$

giving rise to the TDC (“temporal difference learning with corrections”) update of Sutton *et al.* [22]. Here the update of w_t must

use larger step-sizes than the update of θ_t : $\alpha_t = o(\beta_t)$. This makes TDC a member of the family of the so-called *two-timescale stochastic approximation algorithms* [23,24]. If, in addition to this, the standard RM conditions are also satisfied by both step-size sequences, $\theta_t \rightarrow \theta_*$ holds again almost surely [22].

Algorithm 2. The function implementing the GTD2 algorithm. This function must be called after each transition.

function GTD2(X, R, Y, θ, w)

Input: X is the last state, Y is the next state, R is the immediate reward associated with this transition, $\theta \in \mathbb{R}^d$ is the parameter vector of the linear function approximation, $w \in \mathbb{R}^d$ is the auxiliary weight

```

1:  $f \leftarrow \varphi[X]$ 
2:  $f' \leftarrow \varphi[Y]$ 
3:  $\delta \leftarrow R + \gamma \cdot \theta^\top f' - \theta^\top f$ 
4:  $a \leftarrow f^\top w$ 
5:  $\theta \leftarrow \theta + \alpha \cdot (f - \gamma \cdot f') \cdot a$ 
6:  $w \leftarrow w + \beta \cdot (\delta - a) \cdot f$ 
7: return  $(\theta, w)$ 
```

More recently, these algorithms have been extended to nonlinear function approximation [25] and to the $\lambda > 0$ case [26].

Note that although these algorithms are derived from the gradient of an objective function, they are not true stochastic gradient methods in the sense that the expected weight update direction can be different from the direction of the negative gradient of the objective function. In fact, these methods belong to the larger class of pseudogradient methods. The two methods differ in how they approximate the gradients. It remains to be seen whether one of them is better than the other.

LSTD: Least-Squares Temporal Difference Learning. As said earlier, in the limit, TD(0) converges to the solution of Equation (5). Given a finite sample

$$\mathcal{D}_n = ((X_0, R_1, Y_1), (X_1, R_2, Y_2), \dots, (X_{n-1}, R_n, Y_n)),$$

one can approximate Equation (5) by

$$\frac{1}{n} \sum_{t=0}^{n-1} \varphi_t \delta_{t+1}(\theta) = 0. \quad (7)$$

Plugging in $\delta_{t+1}(\theta) = R_{t+1} - (\varphi_t - \gamma \varphi'_{t+1})^\top \theta$, we see that this equation is linear in θ . In particular, if the matrix $\hat{A}_n = \frac{1}{n} \sum_{t=0}^{n-1} \varphi_t (\varphi_t - \gamma \varphi'_{t+1})^\top$ is invertible, the solution is simply

$$\theta_n = \hat{A}_n^{-1} \hat{\delta}_n, \quad (8)$$

where $\hat{\delta}_n = \frac{1}{n} \sum_{t=0}^{n-1} R_{t+1} \varphi_t$.

If inverting the matrix can be afforded (e.g., the dimensionality of the features is not too large and the method is not called too many times), this method can give a better approximation to θ^* than TD(0) or some other incremental first-order method, since the latter are negatively impacted by the eigenvalue spread of the matrix $A = \mathbb{E}[\hat{A}_n]$.

The idea of directly computing the solution of Equation (7) is due to Bradtke and Barto [27], who call the resulting algorithm *least-squares temporal difference* (LSTD) learning. Using the terminology of stochastic programming, LSTD can be seen to use *sample average approximation* [28]. In the terminology of statistics, it belongs to the so-called *Z-estimation* family of procedures [[29], Section 2.2.5].

Algorithm 3. The function implementing the RLSTD algorithm. This function must be called after each transition. Initially, C should be set to a diagonal matrix with small positive diagonal elements: $C = \beta I$, with $\beta > 0$.

function RLSTD(X, R, Y, C, θ)

Input: X is the last state, Y is the next state, R is the immediate reward associated with this transition, $C \in \mathbb{R}^{d \times d}$, and $\theta \in \mathbb{R}^d$ is the parameter vector of the linear function approximation

```

1:  $f \leftarrow \varphi[X]$ 
2:  $f' \leftarrow \varphi[Y]$ 
3:  $g \leftarrow (f - \gamma f')^\top C$   $g$  is a  $1 \times d$  row vector
4:  $a \leftarrow 1 + g f$ 
5:  $v \leftarrow C f$ 
6:  $\delta \leftarrow R + \gamma \cdot \theta^\top f' - \theta^\top f$ 
7:  $\theta \leftarrow \theta + \delta / a \cdot v$ 
8:  $C \leftarrow C - v g / a$ 
9: return ( $C, \theta$ )
```

Using the Sherman–Morrison formula, one can derive an incremental version of LSTD, analogously to how the recursive least-squares (RLS) method is derived in adaptive filtering [30]. The resulting algorithm is called *recursive least-squares temporal difference (RLSTD)* [27] and is shown as Algorithm 3. The computational complexity of one update is $O(d^2)$. When the number of samples n is large, it can be faster to use the direct form of LSTD that uses matrix inversion.

Boyan [31] extended LSTD to incorporate the λ parameter of TD(λ) and called the resulting algorithm LSTD(λ). (Note that for $\lambda > 0$ to make sense one needs $X_{t+1} = Y_{t+1}$, otherwise the TD errors do not telescope.) The recursive form of LSTD(λ), RLSTD(λ), has been studied by Xu *et al.* [32] and (independently) by Nedić and Bertsekas [33].

An alternative to LSTD (and LSTD(λ)) is λ *least-squares policy evaluation* (λ -LSPE for short) due to Bertsekas and Ioffe [34], which implements a form of fitted-value iteration.

Comparing Least-Squares and TD-Like Methods. To compare the two approaches, fix some time T available for computation and assume that samples are cheap to obtain (e.g., an efficient simulator is available). In time T , the least-squares methods are limited to process a sample of size $n \approx T/d^2$, while the lightweight methods can process a sample of size $n' \approx nd$. Let us now look at the precision of the resulting parameters. Assume

that the limit of the parameters is θ_* . Denote by θ_t the parameter obtained by (say) LSTD after processing t observations and denote by θ'_t the parameter obtained by a TD method. Then, one expects that $\|\theta_t - \theta_*\| \approx C_1 t^{-\frac{1}{2}}$ and $\|\theta'_t - \theta_*\| \approx C_2 t^{-\frac{1}{2}}$. Thus,

$$\frac{\|\theta'_{n'} - \theta_*\|}{\|\theta_n - \theta_*\|} \approx \frac{C_2}{C_1} d^{-\frac{1}{2}}. \quad (9)$$

Hence, if $C_2/C_1 < d^{1/2}$ then the lightweight TD-like method will achieve a better accuracy, while in the opposite case the least-squares procedures will perform better. As usual, it is difficult to decide this *a priori*. As a rule of thumb, based on Equation (8), we expect that when d is relatively small, least-squares methods might be converging faster, while if d is large then the lightweight, incremental methods will give better results. Notice that this analysis is not specific to RL methods, but applies in all cases when an incremental lightweight procedure is compared to a least-squares-like procedure and samples are cheap (for a similar analysis in a supervised learning problem, see, e.g., Bottou and Bousquet [35]). One attempt to marry the advantages of the computational efficiency of incremental methods and the statistical efficiency of least-squares methods is described by Geramifard *et al.* [36].

Figure 3. Types of reinforcement problems.

CONTROL

Figure 3 shows the basic types of control learning problems. The first criterion that the space of problems is split upon is whether the learner can actively influence the observations. In case she can, we talk about *interactive learning*, otherwise one is facing a *noninteractive learning* problem. Interactive learning is potentially easier since the learner has the additional option to influence the distribution of the sample. However, the goal of learning, is usually different in the two cases, making these problems incomparable in general.

In the case of noninteractive learning, the natural goal is to find a good policy given the observations. A common situation is when the sample is fixed. For example, the sample can be the result of some experimentation with some physical system that happened before learning started. In machine learning terms, this corresponds to *batch learning*. (Batch learning problems are not to be confused with batch learning methods, which are the opposite of incremental, also known as *recursive* or *iterative* methods.) Since the observations are uncontrolled, the learner working with a fixed sample has to deal with an off-policy learning situation. In other cases, the learner can ask for more data (i.e., when a simulator is used to generate new data). Here, the goal might be to learn a good policy as quickly as possible.

Consider now interactive learning. One possibility is that learning happens while interacting with a real system in a closed-loop manner. A reasonable goal then is to optimize *on-line performance*, making the learning problem an instance of *on-line learning*. In on-line learning, the key is to explore in a clever manner.

On-line performance can be measured in different ways. A natural measure is to use the sum of rewards incurred during learning. If this is offset by the expected sum of rewards under the optimal policy, one gets the notion of regret. Auer *et al.* [37] describe a state-of-the-art algorithm, UCRL2, that works in finite MDPs and give an overview of previous results. An alternative cost measure is the number of times the learner's future expected return falls short of the optimal return, that is, the number of times the learner commits a "mistake" [38]. Szita and Szepesvári [39] review the literature on this and describe a state-of-the-art algorithm, MORMAX, that commits a polynomial number of "mistakes" in finite MDPs. Another possible goal is to produce a well-performing policy as soon as possible (or find a good policy given a finite number of samples), just like in noninteractive learning. As opposed to the noninteractive situation, however, here the learner has the option to control the samples so as to maximize the chance of finding such a good policy. This learning problem is an instance of *active learning*. The E^3 -algorithm of Kearns and Singh [40] explores an unknown MDP and stops when it knows a good policy for the state *just visited*. E^3 needs a polynomial number of interactions and uses poly-resources in the relevant parameters of the problem before it stops. In a follow-up work, Brafman and Tennenholtz [41] introduced the R-max algorithm which refines the E^3 algorithm and proved similar results.

There exist only a few experimental studies in on-line learning. Jong and Stone [42] proposed a method that can be interpreted as a practical implementation of the ideas in Kakade *et al.* [38], while Nouri and Littman [43] experimented with multiresolution regression trees and the so-called fitted Q-iteration algorithm (reviewed in the next section). The main message of these works is that explicit exploration control can indeed be beneficial.

When a simulator is available, the learning algorithms can be used to solve *planning problems*. In planning, on-line learning becomes irrelevant and the algorithms'

running time and memory requirements become the primary concern. Kearns *et al.* [44], Szepesvári [45], Kocsis and Szepesvári [46], and Chang *et al.* [9] discuss some ideas for planning.

When the state or action space is large, one needs to resort to function approximation. Therefore, in what follows, we focus on the core algorithmic problem of learning good controllers in large spaces when a function approximation method is used and neglect the exploration issue. With this we do not want to imply that clever exploration methods are unimportant, but we merely make the point that the clever methods will need to work with efficient methods that use function approximation.

Algorithm 4. The function implementing the Q -learning algorithm with linear function approximation. This function must be called after each transition.

function QLEARNINGLINFAPP(X, A, R, Y, θ)

Input: X is the last state, Y is the next state, R is the immediate reward associated with this transition, $\theta \in \mathbb{R}^d$ parameter vector
 1: $\delta \leftarrow R + \gamma \cdot \max_{a' \in \mathcal{A}} \theta^\top \varphi[Y, a'] - \theta^\top \varphi[X, A]$
 2: $\theta \leftarrow \theta + \alpha \cdot \delta \cdot \varphi[X, A]$
 3: **return** θ

Although Q -learning is widely used in practice, little can be said about its convergence properties. In fact, since $\text{TD}(\lambda)$ is a special case of this algorithm (when there is only one action for every state), just like $\text{TD}(\lambda)$, this update rule will also fail to converge when off-policy sampling or nonlinear function approximation is used (cf. the section titled “ $\text{TD}(\lambda)$ with Linear Function Approximation”).

Algorithm 5. The function implementing one iteration of the fitted Q -iteration algorithm. The function must be called until some criterion of convergence is met. The methods `PREDICT` and `REGRESS` are specific to the regression method chosen. The method `PREDICT( $z, \theta$ )` should return the predicted value at the input z given the regression parameters θ , while `REGRESS( $S$ )`, given a list of input–output pairs S , should implement a regression algorithm that solves the regression problem given by S and returns new parameters that can be used in `PREDICT`.

function FITTEDQ(D, θ)

Input: $D = ((X_i, A_i, R_{i+1}, Y_{i+1}); i = 1, \dots, n)$ is a list of transitions, θ are the regressor parameters
 1: $S \leftarrow []$ ▷ Create empty list
 2: **for** $i = 1 \rightarrow n$ **do**
 3: $T \leftarrow R_{i+1} + \max_{a' \in \mathcal{A}} \text{predict}((Y_{i+1}, a'), \theta)$ ▷ Target at (X_i, A_i)
 4: $S \leftarrow \text{APPEND}(S, (X_i, A_i, T))$
 5: **end for**
 6: $\theta \leftarrow \text{REGRESS}(S)$
 7: **return** θ

Direct Methods

Direct methods aim at approximating the optimal action-value function directly. One class of methods, two members of which are reviewed here, can be thought of as implementing a form of value iteration with action-value functions.

Q -Learning with Function Approximation.

Assume that we are given features $\varphi(x, a) \in \mathbb{R}^d$ of state-action pairs. The problem is to find weights $\theta \in \mathbb{R}^d$ such that $Q^*(x, a) \approx \theta^\top \varphi(x, a)$ holds for all $(x, a) \in \mathcal{X} \times \mathcal{A}$. The Q -learning algorithm by Watkins [47], whose update is shown as Algorithm 4, can be thought of as the extension of $\text{TD}(\lambda)$ to this case.

Fitted Q -Iteration. Fitted Q -iteration is an instance of the generic fitted-value iteration recipe. Given the previous iterate, Q_t , the idea is to form a Monte Carlo approximation to $T^*Q_t(x, a)$ at select state-action pairs and then learn a regressor based on the so-created data set. Algorithm 5 shows the corresponding pseudocode. This method must be called repeatedly in a loop until convergence.

It is known that fitted Q -iteration might diverge unless a special regressor is used [20,21,48].

Ormoneit and Sen [49] suggest to use kernel averaging, while Ernst *et al.* [50] suggest using tree-based regressors. These are guaranteed to converge (say, if the same data is fed to the algorithm in each iteration) as they implement local averaging and therefore the results of Gordon [51] and Tsitsiklis and Van Roy [48] are applicable to them. Riedmiller [52] reports good empirical results with neural networks, at least when new observations obtained by following a policy greedy with respect to the latest iterate are incrementally added to the set of samples used in the updates. That the sample is changed is essential if no good initial policy is available, that is, when in the initial sample the states that are frequently visited by “good” policies are underrepresented (a theoretical argument for why this is important is given by Van Roy [53] in the context of state aggregation).

Antos *et al.* [54] and Munos and Szepesvári [55] prove finite-sample performance bounds that apply to a large class of regression methods that use empirical risk minimization over a fixed space $\mathcal{F}$ of candidate action-value functions. Their bounds depend on the *worst-case Bellman error* of $\mathcal{F}$:

$$e_1^*(\mathcal{F}) = \sup_{Q \in \mathcal{F}} \inf_{Q' \in \mathcal{F}} \|Q' - T^*Q\|_\mu,$$

where μ is the distribution of state-action pairs in the training sample. That is, $e_1^*(\mathcal{F})$ measures how close $\mathcal{F}$ is to $T^*\mathcal{F} \stackrel{\text{def}}{=} \{T^*Q \mid Q \in \mathcal{F}\}$. The bounds derived have the form of the finite-sample bounds that hold in supervised learning, except that the approximation error is measured by $e_1^*(\mathcal{F})$. Note that in the earlier-mentioned counterexamples to the convergence of fitted-value iteration, $e_1^*(\mathcal{F}) = \infty$, suggesting that it is the lack of flexibility of the function approximation method that causes divergence.

Figure 4. The actor-critic architecture.

Actor-Critic Methods

Actor-critic methods implement generalized policy iteration (GPI). Remember that policy iteration works by alternating between a complete policy evaluation and a complete policy improvement step. When using sample-based methods or function approximation, exact evaluation of the policies may require infinitely many samples or might be impossible due to the restrictions of the function approximation technique. Hence, RL algorithms simulating policy iteration must change the policy based on incomplete knowledge of the value function.

Algorithms that update the policy before it is completely evaluated are said to implement GPI. In GPI, there are two closely interacting processes of an actor and a critic: the actor aims at improving the current policy, while the critic evaluates the current policy, thus helping the actor. The interaction of the actor and the critic is illustrated in Figure 4 in a closed-loop learning situation.

Implementing a Critic. The job of the critic is to estimate the value of the current target policy of the actor. This is a value prediction problem. Therefore, the critic can use any value prediction method. Since the actor needs action values, the algorithms are typically modified so that they estimate action values directly. When $TD(\lambda)$ is appropriately extended, the algorithm known as SARSA(λ) is obtained due to Rummery and Niranjan [56]. The algorithm is named from its use of the current State, current Action, next Reward, next State, and next Action. The

pseudocode of the corresponding update rule is shown as Algorithm 6.

Being a TD algorithm, the resulting algorithm is subject to the same limitations as TD(λ) (cf. the section titled “TD(λ) with Linear Function Approximation”), that is, it might diverge in off-policy situations. It is, however, possible to extend GTD2 and TDC to work with action values (and use $\lambda > 0$) so that the resulting algorithms would become free of these limitations. For details consult Maei and Sutton [26].

Algorithm 6. The function implementing the SARSA(λ) algorithm with linear function approximation. This function must be called after each transition.

function SALSALAMBDA LINFAPP($X, A, R, Y, A', \theta, z$)

Input: X is the last state, A is the last action chosen, R is the immediate reward received when transitioning to Y , where action A' is chosen. $\theta \in \mathbb{R}^d$ is the parameter vector of the linear function approximation, $z \in \mathbb{R}^d$ is the vector of eligibility traces

- 1: $\delta \leftarrow R + \gamma \cdot \theta^\top \varphi[Y, A'] - \theta^\top \varphi[X, A]$
- 2: $z \leftarrow \varphi[X, A] + \gamma \cdot \lambda \cdot z$
- 3: $\theta \leftarrow \theta + \alpha \cdot \delta \cdot z$
- 4: **return** (θ, z)

Consider a smoothly parameterized policy class $\Pi = (\pi_\omega; \omega \in \mathbb{R}^{d_\omega})$ of stochastic stationary policies. When the action space is finite, a popular choice for Π is to use the so-called *Gibbs policies*:

$$\pi_\omega(a|x) = \frac{\exp(\omega^\top \xi(x, a))}{\sum_{a' \in \mathcal{A}} \exp(\omega^\top \xi(x, a'))},$$

$x \in \mathcal{X}, a \in \mathcal{A}.$

Here, $\xi : \mathcal{X} \times \mathcal{A} \rightarrow \mathbb{R}^{d_\omega}$ is an appropriate feature-extraction function. On the other hand, if the action space is a subset of a $d_{\mathcal{A}}$ -dimension Euclidean space, a popular choice is to use the Gaussian policies, in which case, given some parametric mean $g_\omega(x, a)$ and covariance $\Sigma_\omega(x, a)$ functions, the density specifying the action-selection distribution under ω is defined by

$$\begin{aligned} \pi_\omega(a|x) = & \frac{1}{\sqrt{(2\pi)^{d_{\mathcal{A}}} \det(\Sigma_\omega(x, a))}} \\ & \times \exp(-(a - g_\omega(x, a))^\top \\ & \times \Sigma_\omega^{-1}(x, a)(a - g_\omega(x, a))). \end{aligned}$$

Implementing an Actor. Policy improvement can be implemented in two ways: One idea is moving the current policy toward the greedy policy underlying the approximate action-value function obtained from the critic. Another idea is to perform gradient ascent directly on the performance surface underlying a chosen parametric policy class. Here, we describe a method based on the latter idea.

Care must be taken to ensure that Σ_ω is positive definite. Often, for simplicity, Σ_ω is taken to be $\Sigma_\omega = \beta I$ with some $\beta > 0$.

Given Π , formally, the problem is to find the value of ω corresponding to the best performing policy:

$$\operatorname{argmax}_{\omega} \rho_\omega = ?$$

Here, the performance, ρ_ω , is usually the expected return of policy π_ω with respect to the initial distribution over the states.

One possible actor-critic algorithm is shown in Algorithm 7. A special assumption in this method is that the features ψ_ω used by SARSA(λ), called in line 6, are *compatible* with π_ω in the sense that $\psi_\omega(x, a) = \frac{\partial}{\partial \omega} \log \pi_\omega(x, a)$. Note that the features depend on the value of ω , which, in the pseudocode, is signified by the presence of ω as a subindex to SALSALAMBDA LINFAPP. Konda and Tsitsiklis [57] proved that (under some regularity conditions) $\liminf_{t \rightarrow \infty} \nabla_\omega \rho_{\omega_t} = 0$ holds almost surely if the average-cost version of SARSA(1) is used to update θ_t . They have also shown that if SARSA(λ) is used and $m_\lambda = \liminf_{t \rightarrow \infty} \nabla_\omega \rho_{\omega_t}$, then $\lim_{\lambda \rightarrow 1} m_\lambda = 0$.

Algorithm 7. An actor-critic algorithm that uses compatible function approximation and SARSA(1).

```

function SARSAACTORCRITIC
1:  $\omega, \theta, z \leftarrow 0$ 
2:  $A \leftarrow a'_1$ 
3: repeat
4:    $(R, Y) \leftarrow \text{EXECUTEINWORLD}(A)$ 
5:    $A' \leftarrow \text{DRAW}(\pi_\omega(Y, \cdot))$ 
6:    $(\theta, z) \leftarrow \text{SARSALAMBDALINFAPP}_\omega(X, A, R, Y, A', \theta, z)$   $\triangleright$  Use  $\lambda = 1$  and  $\alpha \gg \beta$ 
7:    $\psi \leftarrow \frac{\partial}{\partial \omega} \log \pi_\omega(X, A)$ 
8:    $v \leftarrow \text{SUM} \pi_\omega(Y, \cdot) \cdot \theta^\top \varphi[X, \cdot]$ 
9:    $\omega \leftarrow \omega + \beta \cdot (\theta^\top \varphi[X, A] - v) \cdot \psi$ 
10:   $X \leftarrow Y$ 
11:   $A \leftarrow A'$ 
12: until True

```

Another interesting algorithm is obtained if one replaces the update in line 9 with

$$\omega \leftarrow \omega + \beta \cdot \theta,$$

which is called the *natural actor-critic* (NAC) update. Under some mild conditions, this algorithm can be seen to implement a stochastic pseudogradient algorithm, and thus the previous results extend to it.

For a fixed value of ω , the limit of the SARSA update, $\theta_*(\omega)$, can be shown to be a so-called *natural gradient* [58] of ρ_ω . This was first noted by Kakade [59]. It is believed that following a natural gradient generally improves the behavior of gradient ascent methods. This is nicely demonstrated by Kakade [59] on a simple two-state MDP, where the “normal” gradient is very small in a large part of the parameter space, while the natural gradient behaves in a reasonable manner. Other positive examples were given by Bagnell and Schneider [60], Peters *et al.* [61], and Peters and Schaal [62].

FOR FURTHER EXPLORATION

Inevitably, due to space constraints, in this review a large portion of the RL literature has not been mentioned.

One topic of particular interest not discussed is efficient sampling-based planning [9, 44–46]. The main lesson here is that off-line planning in the worst case can scale exponentially with the dimensionality of the

state space [63], while on-line planning (i.e., planning for the “current state”) can break the curse of dimensionality by amortizing the planning effort over multiple time steps [45, 64].

Other topics of interest include the linear programming-based approaches [65–67], dual dynamic programming [68], techniques based on sample average approximation [28] such as PEGASUS [69], on-line learning in MDPs with arbitrary reward processes [70–72], or learning with (almost) no restrictions in a competitive framework [73].

Other important topics include learning and acting in partially observed MDPs (for recent developments, see, e.g., Littman *et al.* [74], Toussaint *et al.* [75], Ross *et al.* [76]), learning and acting in games or under some other optimization criteria [77–80], or the development of hierarchical and multi-time-scale methods [81, 82].

Applications

The numerous successful applications of RL include (in no particular order) games, for example, Backgammon [83] and Go [84]; applications in networking, for example, packet routing [85] and channel allocation [86]; various operations research problems, for example, targeted marketing [87], maintenance problems [88], job-shop scheduling [89], elevator control [90], pricing [91], vehicle routing [92], inventory control [93], and fleet management [94]; learning in robotics, for example, controlling quadrupedals [95],

humanoid robots [61], or helicopters [96]; and finance, for example, option pricing [97–100]. For further applications, see, for example, the lists at the URLs

- <http://umichrl.pbworks.com/Successes-of-Reinforcement-Learning>.

Software

There are numerous software packages that support the development and testing of RL algorithms. Perhaps the most notable of these are the RL-GLUE and RL-LIBRARY packages. The RL-GLUE package available at <http://glue.rl-community.org> is intended for helping to standardize RL experiments. It is a free, language-neutral software package that implements a standardized RL interface [101]. The RL-LIBRARY (<http://library.rl-community.org>) builds on the top of RL-GLUE. Its purpose is to provide trusted implementations of various RL test beds and algorithms. The most notable other RL software packages are CLSquare,⁴ PIQLE,⁵ RL Toolbox,⁶ JRLF⁷, and LibPG.⁸ These offer the implementation of a large number of algorithms, test beds, intuitive visualizations, programming tools, and so on. Many of these packages support RL-GLUE.

RELATIONSHIP AMONG BENDERS, DANTZIG–WOLFE, AND LAGRANGIAN OPTIMIZATION

CHURLZU LIM

University of North Carolina at
Charlotte, Charlotte, North
Carolina

When solving a linear programming problem, Benders decomposition, Dantzig–Wolfe decomposition, and Lagrangian optimization can be interpreted as equivalent techniques applied to different representations of the problem such as primal linear, and Lagrangian dual formulations. In particular, applying Dantzig–Wolfe decomposition to a linear program is equivalent to employing Benders decomposition to solve its dual linear program, and implementing a cutting plane method to solve its Lagrangian dual problem (Fig. 1). To illustrate their equivalence, consider the following linear program:

$$\mathbf{P}: \quad \text{Minimize} \quad \mathbf{c}^T \mathbf{x} + \mathbf{d}^T \mathbf{y} \quad (1a)$$

$$\text{subject to} \quad \mathbf{Ax} + \mathbf{Dy} = \mathbf{b}, \quad (1b)$$

$$\mathbf{Fx} = \mathbf{g}, \quad (1c)$$

$$\mathbf{x} \geq \mathbf{0}, \quad \mathbf{y} \geq \mathbf{0}, \quad (1d)$$

where $\mathbf{c}, \mathbf{x} \in \mathbb{R}^n$, $\mathbf{d}, \mathbf{y} \in \mathbb{R}^l$, $\mathbf{A} \in \mathbb{R}^{m \times n}$, $\mathbf{D} \in \mathbb{R}^{m \times l}$, $\mathbf{b} \in \mathbb{R}^m$, $\mathbf{F} \in \mathbb{R}^{k \times n}$, $\mathbf{g} \in \mathbb{R}^k$, and $\mathbf{0}$ s are vectors of zeros having appropriate dimensions. All vectors are defined as column vectors, and T denotes a transpose operator. Suppose that constraints in Equation (1b) are *complicating* (or *coupling*) constraints where both $\mathbf{x}$ and $\mathbf{y}$ appear in the constraints, while those in Equation (1c) are relatively simple. Using this specially structured linear program, we first present the equivalence between Dantzig–Wolfe decomposition and Benders decomposition; this is followed by demonstration of the equivalence between Benders decomposition and Lagrangian optimization. We also verify the equivalence when they are applied to block diagonal structures.

EQUIVALENCE OF DANTZIG–WOLFE DECOMPOSITION AND BENDERS DECOMPOSITION

Assume that the optimal objective value of $\mathbf{P}$ is finite. Furthermore, in order to avoid cumbersome presentation, let us assume that the polyhedral set $\mathbf{X} \equiv \{\mathbf{x} : \mathbf{Fx} = \mathbf{g}, \mathbf{x} \geq \mathbf{0}\}$ is nonempty and bounded. (We will briefly discuss the case of unbounded polyhedral sets later.) Then, each $\mathbf{x} \in \mathbf{X}$ can be written as a convex combination of a finite number of extreme points. Letting $E_{\mathbf{X}}$ denote the index set of extreme points in $\mathbf{X}$, we have

$$\mathbf{X} = \left\{ \sum_{j \in E_{\mathbf{X}}} \lambda_j \mathbf{x}_j : \sum_{j \in E_{\mathbf{X}}} \lambda_j = 1, \lambda_j \geq 0 \forall j \in E_{\mathbf{X}} \right\}, \quad (2)$$

Replacing $\mathbf{X}$ by Equation (2), we can rewrite $\mathbf{P}$ as

DW-MP:

$$\text{Minimize} \quad \sum_{j \in E_{\mathbf{X}}} (\mathbf{c}^T \mathbf{x}_j) \lambda_j + \mathbf{d}^T \mathbf{y} \quad (3a)$$

$$\text{subject to} \quad \sum_{j \in E_{\mathbf{X}}} (\mathbf{Ax}_j) \lambda_j + \mathbf{Dy} = \mathbf{b}, \quad (3b)$$

$$\sum_{j \in E_{\mathbf{X}}} \lambda_j = 1, \quad (3c)$$

$$\lambda_j \geq 0 \quad \text{for } j \in E_{\mathbf{X}}, \quad \mathbf{y} \geq \mathbf{0}. \quad (3d)$$

Note that **DW-MP** is the *Dantzig–Wolfe master program* of Dantzig–Wolfe decomposition (see **Dantzig–Wolfe Decomposition**). The decomposition algorithm commences with a master program having a subset of extreme points, which is called a *restricted master program*. $\mathbf{x}_j$'s and λ_j 's are iteratively added to this restricted master program when its solution is not optimal to **DW-MP**. Optimality is checked by solving the following subproblem:

DW-SP:

$$\text{Minimize} \quad \mathbf{c}^T \mathbf{x} - \bar{\mathbf{u}}^T \mathbf{Ax} - \bar{z} \quad (4a)$$

$$\text{subject to} \quad \mathbf{x} \in \mathbf{X}, \quad (4b)$$

Figure 1. Schematic relationship of three decomposition methods.

where $\bar{\mathbf{u}}$ and $\bar{z}$ are the dual solutions of the current restricted master program. Note that the objective function of **DW-SP** (the Dantzig–Wolfe subproblem) represents the *reduced cost* of **DW-MP** (see *The Simplex Method and Its Complexity* and *Dual Simplex*). If the optimal objective value of **DW-SP** is nonnegative, then no extreme point in $\mathbf{X}$ yields negative reduced costs for **DW-MP** at the current basic feasible solution (see *The Simplex Method and Its Complexity*), and hence, the solution to the current restricted master program is also optimal to **DW-MP**. Otherwise, an entering variable λ_{j+1} that corresponds to the solution of **DW-SP**, $\mathbf{x}_{j+1}$, is added to the restricted master program to generate a new column (see Ref. 1; **Dantzig–Wolfe Decomposition** and **Column Generation**).

Since $\mathbf{P}$ is assumed to have a finite optimal objective value, solving its dual linear program will yield the optimal solution to $\mathbf{P}$ (see *LP Duality and KKT Conditions for LP*). Let $\mathbf{u}$ and $\mathbf{v}$ denote dual variable vectors associated with the constraints in Equations (1b) and (1c), respectively. Then, the dual linear program of $\mathbf{P}$ is as follows:

$$\begin{aligned} \mathbf{D}: \quad & \text{Maximize } \mathbf{b}^T \mathbf{u} + \mathbf{g}^T \mathbf{v} \\ & \text{subject to } \mathbf{A}^T \mathbf{u} + \mathbf{F}^T \mathbf{v} \leq \mathbf{c}, \\ & \mathbf{D}^T \mathbf{u} \leq \mathbf{d}. \end{aligned}$$

Let us first derive the master program of Benders decomposition for problem $\mathbf{D}$. Delaying the decision on $\mathbf{v}$, the dual linear

program can be written as

$$\text{Maximize}_{\mathbf{u} \in \mathbf{U}} \mathbf{b}^T \mathbf{u} + \left[\max_{\mathbf{v}} \mathbf{g}^T \mathbf{v} \right. \\ \left. \text{s.t. } \mathbf{F}^T \mathbf{v} \leq \mathbf{c} - \mathbf{A}^T \mathbf{u} \right], \quad (5)$$

where $\mathbf{U} = \{\mathbf{u} : \mathbf{D}^T \mathbf{u} \leq \mathbf{d}\}$.

Given $\bar{\mathbf{u}} \in \mathbf{U}$, let $\mathbf{x}$ be the dual variable vector of the inner maximization problem. Then, the dual linear program of the inner maximization problem becomes

$$\text{Minimize } (\mathbf{c} - \mathbf{A}^T \bar{\mathbf{u}})^T \mathbf{x} \quad (6a)$$

$$\text{subject to } \mathbf{x} \in \mathbf{X}. \quad (6b)$$

Since $\mathbf{X}$ is nonempty and bounded, the inner maximization problem in Equation (5) and the problem in Equation (6) will yield the same optimal objective value, which can be alternately obtained via

$$\min_{j \in E_{\mathbf{X}}} \{(\mathbf{c} - \mathbf{A}^T \bar{\mathbf{u}})^T \mathbf{x}_j\}, \quad (7)$$

where again $E_{\mathbf{X}}$ is the index set of extreme points of $\mathbf{X}$. Finally, substituting the minimum value in Equation (7) with a variable z , the problem in Equation (5) can be written as the following Benders master program (B-MP):

B-MP:

$$\text{Maximize } \mathbf{b}^T \mathbf{u} + z \quad (8a)$$

$$\text{subject to } \mathbf{D}^T \mathbf{u} \leq \mathbf{d}, \quad (8b)$$

$$z + (\mathbf{A} \mathbf{x}_j)^T \mathbf{u} \leq \mathbf{c}^T \mathbf{x}_j \\ \text{for } j \in E_{\mathbf{X}}. \quad (8c)$$

Note from Equation (8c) that z represents a lower bound of $\{(\mathbf{c} - \mathbf{A}^T \mathbf{u})^T \mathbf{x}_j : j \in E_{\mathbf{X}}\}$. Furthermore, maximizing the objective value of **B-MP** guarantees that the optimal value of z is indeed the greatest lower bound (i.e., $\min_{j \in E_{\mathbf{X}}} \{(\mathbf{c} - \mathbf{A}^T \mathbf{u})^T \mathbf{x}_j\}$).

Benders decomposition algorithm begins with a subset of constraints of **B-MP** (hence, it is called the *relaxed* master program), and then iteratively adds constraints along with new $\mathbf{x}_j$'s when the solution of the current relaxed master program is infeasible to **B-MP**. Given the current solution $(\bar{\mathbf{u}}, \bar{z})$, infeasibility is checked by solving the following subproblem:

$$\begin{aligned} \text{B-SP:} \quad & \text{Minimize} \quad \mathbf{c}^T \mathbf{x} - \bar{\mathbf{u}}^T \mathbf{A} \mathbf{x} \\ & \text{subject to} \quad \mathbf{x} \in \mathbf{X}. \end{aligned}$$

If its optimal objective value is not less than $\bar{z}$, it implies that the current solution satisfies all the constraints in **B-MP**. Otherwise, a new constraint is added to the relaxed master program (see Ref. 2, **Benders Decomposition**).

Let $\mathbf{y}$ and λ_j for $j \in E_{\mathbf{X}}$ denote the dual variable vector and dual variables associated with constraints given in Equations (8b) and (8c), respectively. Then, the dual linear program of **B-MP** becomes

$$\begin{aligned} & \text{Minimize} \quad \mathbf{d}^T \mathbf{y} + \sum_{j \in E_{\mathbf{X}}} (\mathbf{c}^T \mathbf{x}_j) \lambda_j \\ & \text{subject to} \quad \sum_{j \in E_{\mathbf{X}}} \lambda_j = 1, \\ & \quad \mathbf{D} \mathbf{y} + \sum_{j \in E_{\mathbf{X}}} (\mathbf{A} \mathbf{x}_j) \lambda_j = \mathbf{b}, \\ & \quad \lambda_j \geq 0 \forall j \in E_{\mathbf{X}}, \mathbf{y} \geq \mathbf{0}. \end{aligned}$$

This problem is identical to the master program of Dantzig–Wolfe decomposition in Equation (3). Furthermore, **DW-SP** is also equivalent to **B-SP** (Benders subproblem). Hence, we can conclude that the Dantzig–Wolfe decomposition method for solving the primal linear program **P** is equivalent to the Benders decomposition method for solving the dual linear program **D**.

EQUIVALENCE OF BENDERS DECOMPOSITION AND LAGRANGIAN OPTIMIZATION

Next, we present how the Lagrangian optimization for linear programs can be related to Benders decomposition. Let $\mathbf{u}$ denote the *Lagrangian multiplier* vector associated with the complicating constraints (Eq. 1b). Lifting the complicating constraints, we have the following *Lagrangian relaxation* (see Ref. 3, **Lagrangian Optimization for LP**)

$$\begin{aligned} \theta(\mathbf{u}) = \text{Minimize} \quad & \mathbf{c}^T \mathbf{x} + \mathbf{d}^T \mathbf{y} + \mathbf{u}^T \\ & \times (\mathbf{b} - \mathbf{A} \mathbf{x} - \mathbf{D} \mathbf{y}) \\ & \text{subject to} \quad \mathbf{F} \mathbf{x} = \mathbf{g} \\ & \quad \mathbf{x} \geq \mathbf{0}, \mathbf{y} \geq \mathbf{0}, \end{aligned}$$

where $\theta(\mathbf{u})$ is called the *Lagrangian function*. Then, the Lagrangian dual problem is to find the maximum value of the Lagrangian function:

LD:

$$\begin{aligned} \text{Maximize} \quad \theta(\mathbf{u}) = & \mathbf{u}^T \mathbf{b} + \min_{\mathbf{x} \in \mathbf{X}} (\mathbf{c}^T - \mathbf{u}^T \mathbf{A}) \mathbf{x} \\ & + \min_{\mathbf{y} \geq \mathbf{0}} (\mathbf{d}^T - \mathbf{u}^T \mathbf{D}) \mathbf{y}. \end{aligned}$$

Recall that **P** has a finite optimal objective value. Since **P** is a linear program having a feasible solution, **P** and **LD** yield the same optimal objective value.

The second minimization in $\theta(\mathbf{u})$ has a trivial solution; $\mathbf{y} = \mathbf{0}$ for $\mathbf{u}$ such that $\mathbf{u}^T \mathbf{D} \leq \mathbf{d}$, while it has an unbounded objective value if the inequality does not hold. Note that there exists $\mathbf{u}$ satisfying $\mathbf{u}^T \mathbf{D} \leq \mathbf{d}$ (otherwise, linear program **P**, and in turn **D**, do not have a bounded optimal objective value). Therefore, we can rewrite **LD** as follows:

LD:

$$\begin{aligned} \text{Maximize}_{\mathbf{u} \in \mathbf{U}} \quad \theta(\mathbf{u}) = & \mathbf{b}^T \mathbf{u} + \min_{\mathbf{x} \in \mathbf{X}} (\mathbf{c}^T - \mathbf{u}^T \mathbf{A}) \mathbf{x}. \end{aligned} \tag{9}$$

Note that this **LD** is identical to the problem in Equation (5) where the inner problem is replaced by Equation (6). Using Equation (7) and substituting the minimum value with a

single variable z , the master problem of the cutting plane algorithm for solving **LD** is

L-MP:

$$\begin{aligned} & \text{Maximize } \mathbf{b}^T \mathbf{u} + z, \\ & \mathbf{D}^T \mathbf{u} \leq \mathbf{d}, \\ & z + (\mathbf{Ax}_j)^T \mathbf{u} \leq \mathbf{c}^T \mathbf{x}_j \quad \forall j \in E_{\mathbf{X}}, \end{aligned}$$

which is identical to **B-MP**. Given a solution $(\bar{\mathbf{u}}, \bar{z})$ to the *relaxed* master program, the optimality is checked by solving the following Lagrangian subproblem:

$$\begin{aligned} \text{L-SP:} \quad & \text{Minimize } \mathbf{c}^T \mathbf{x} - \bar{\mathbf{u}}^T \mathbf{Ax} \\ & \text{subject to } \mathbf{x} \in \mathbf{X}, \end{aligned}$$

which is again identical to **B-SP**. Hence, when solving linear programs, the Lagrangian optimization via the cutting plane method is equivalent to Benders decomposition.

UNBOUNDED FEASIBLE REGION OF SUBPROBLEM

In the previous problem, we assumed that $\mathbf{X}$ is nonempty and bounded. When $\mathbf{X}$ is unbounded, Equation (2) can be modified as follows:

$$\mathbf{X} = \left\{ \sum_{j \in E_{\mathbf{X}}} \lambda_j \mathbf{x}_j + \sum_{j \in D_{\mathbf{X}}} \mu_j \mathbf{d}_j : \sum_{j \in E_{\mathbf{X}}} \lambda_j = 1, \right. \\ \left. \lambda_j \geq 0 \quad \forall j \in E_{\mathbf{X}}, \mu_j \geq 0 \quad \forall j \in D_{\mathbf{X}} \right\},$$

where $D_{\mathbf{X}}$ is the index set of extreme directions of $\mathbf{X}$, and $\mathbf{d}^j$, $\forall j \in D_{\mathbf{X}}$, are extreme directions. Then, the master program of Dantzig–Wolfe decomposition becomes

$$\begin{aligned} & \text{Minimize} \\ & \sum_{j \in E_{\mathbf{X}}} (\mathbf{c}^T \mathbf{x}_j) \lambda_j + \sum_{j \in D_{\mathbf{X}}} (\mathbf{c}^T \mathbf{d}_j) \mu_j + \mathbf{d}^T \mathbf{y} \quad (10a) \\ & \text{subject to} \end{aligned}$$

$$\sum_{j \in E_{\mathbf{X}}} (\mathbf{Ax}_j) \lambda_j + \sum_{j \in D_{\mathbf{X}}} (\mathbf{Ad}_j) \mu_j + \mathbf{Dy} = \mathbf{b}, \quad (10b)$$

$$\sum_{j \in E_{\mathbf{X}}} \lambda_j = 1, \quad (10c)$$

$$\lambda_j \geq 0 \quad \forall j \in E_{\mathbf{X}}, \mu_j \geq 0 \quad \forall j \in D_{\mathbf{X}}, \mathbf{y} \geq \mathbf{0}. \quad (10d)$$

Note that the subproblem remains the same as in Equation (4). When the subproblem yields an unbounded solution, an extreme direction is generated and added to the restricted master program.

From the Ref. 2 (see also **Benders Decomposition**), the Benders master program is

$$\text{Maximize } \mathbf{b}^T \mathbf{u} + z \quad (11a)$$

$$\text{subject to } \mathbf{D}^T \mathbf{u} \leq \mathbf{d}, \quad (11b)$$

$$z + (\mathbf{Ax}_j)^T \mathbf{u} \leq \mathbf{c}^T \mathbf{x}_j, \quad \forall j \in E_{\mathbf{X}}, \quad (11c)$$

$$(\mathbf{Ad}_j)^T \mathbf{u} \leq \mathbf{c}^T \mathbf{d}_j, \quad \forall j \in D_{\mathbf{X}}. \quad (11d)$$

One can verify that this master program is indeed the dual linear program of Equation (10).

Finally, note that the Lagrangian dual problem is same as in Equation (9). However, since $\mathbf{X}$ is now unbounded, the inner minimization problem may have an extreme direction along which the objective function value decreases. Such $\mathbf{u}$'s yielding this unboundedness are not of interest in the Lagrangian dual problem that maximizes $\theta(\mathbf{u})$, and hence, we can further restrict the selection of $\mathbf{u}$ such that

$$(\mathbf{c}^T - \mathbf{u}^T \mathbf{A}) \mathbf{d}_j \geq 0, \quad \forall j \in D_{\mathbf{X}}.$$

Equivalently, this can be written as

$$(\mathbf{Ad}_j)^T \mathbf{u} \leq \mathbf{c}^T \mathbf{d}_j, \quad \forall j \in D_{\mathbf{X}}.$$

Given that $\mathbf{u}$ satisfies these constraints, the minimum of the inner problem can be identified as Equation (7) and the master program of cutting plane method becomes identical to the master program of Benders decomposition in Equation (11).

$$\text{Minimize} \quad (\mathbf{c}^1)^T \mathbf{x}^1 + (\mathbf{c}^2)^T \mathbf{x}^2 + \dots + (\mathbf{c}^K)^T \mathbf{x}^K \quad (12a)$$

$$\text{subject to} \quad \mathbf{A}^1 \mathbf{x}^1 + \mathbf{A}^2 \mathbf{x}^2 + \dots + \mathbf{A}^K \mathbf{x}^K = \mathbf{b} \quad (12b)$$

$$\mathbf{D}^1 \mathbf{x}^1 = \mathbf{g}^1 \quad (12c)$$

$$\mathbf{D}^2 \mathbf{x}^2 = \mathbf{g}^2 \quad (12d)$$

$$\ddots = \vdots \quad (12e)$$

$$\mathbf{D}^K \mathbf{x}^K = \mathbf{g}^K \quad (12f)$$

$$\mathbf{x}^1 \quad \mathbf{x}^2 \quad \dots \quad \mathbf{x}^K \geq \mathbf{0}, \quad (12g)$$

where the constraint set can be partitioned into $K + 1$ subsets such that one is the set of complicating constraints (Eq. 12b) and others contain exclusive variable vectors (Eqs 12c–f). (Note that without the complicating constraints, the problem would have been separable to K small linear programs.) Assuming boundedness, each constraint set can be written as convex combinations of extreme points of respective polytopes. (A similar argument can be made when constraints sets are unbounded as before.) Then, the master program of Dantzig–Wolfe decomposition becomes

$$\text{Minimize} \quad \sum_{i=1}^K \sum_{j \in E_{\mathbf{X}^i}} (\mathbf{c}^T \mathbf{x}_j^i) \lambda_j^i \quad (13a)$$

$$\text{subject to} \quad \sum_{i=1}^K \sum_{j \in E_{\mathbf{X}^i}} (\mathbf{A}^i \mathbf{x}_j^i) \lambda_j^i = \mathbf{b}, \quad (13b)$$

$$\sum_{j \in E_{\mathbf{X}^i}} \lambda_j^i = 1, \quad i = 1, \dots, K \quad (13c)$$

$$\lambda_j^i \geq 0, \quad \forall i = 1, \dots, K, \forall j \in E_{\mathbf{X}^i}, \quad (13d)$$

where $E_{\mathbf{X}^i}$ is the index set of extreme points of $\mathbf{X}^i = \{\mathbf{x}^i : \mathbf{D}^i \mathbf{x} = \mathbf{g}^i, \mathbf{x}^i \geq \mathbf{0}\}$. Accordingly, the following K subproblems, for $i = 1, \dots, K$, need to be solved to check optimality of the current solution.

$$\begin{aligned} &\text{Minimize} \quad (\mathbf{c}^i)^T \mathbf{x}^i - (\bar{\mathbf{u}})^T \mathbf{A}^i \mathbf{x}^i - \bar{z}^i \\ &\text{subject to} \quad \mathbf{x}^i \in \mathbf{X}^i, \end{aligned}$$

where $\bar{\mathbf{u}}$ and $\bar{z}^i$ are dual solutions corresponding to Equations (13b) and (13c), respectively. On the other hand, the Benders master program of Equation (12) is

$$\text{Minimize} \quad \mathbf{b}^T \mathbf{u} + \sum_{i=1}^K z^i \quad (14a)$$

$$\begin{aligned} &\text{subject to} \quad z^i + (\mathbf{A}^i \mathbf{x}_j^i)^T \mathbf{u} \leq (\mathbf{c}^i)^T \mathbf{x}_j^i, \\ &\quad \forall i = 1, \dots, K, \forall j \in E_{\mathbf{X}^i}. \end{aligned} \quad (14b)$$

Again, one can see that this master program is the dual linear program of Equation (13).

Dualizing complicating constraints (Eq. 12b), the Lagrangian dual problem of Equation (12) can be written as follows:

$$\begin{aligned} &\text{Maximize} \\ &\theta(\mathbf{u}) = \mathbf{b}^T \mathbf{u} + \sum_{i=1}^K \min_{\mathbf{x}^i \in \mathbf{X}^i} [(\mathbf{c}^T)^i - \mathbf{u}^T \mathbf{A}^i] \mathbf{x}^i. \end{aligned}$$

Then, letting $z^i = \min_{\mathbf{x}^i \in \mathbf{X}^i} \{[(\mathbf{c}^T)^i - \mathbf{u}^T \mathbf{A}^i] \mathbf{x}^i\}$,

the master program of the cutting plane method is identical to Equation (14).

For details about various decomposition methods applied to linear and nonlinear programs and stochastic programming, readers are referred to Refs 3–5, and sections titled “Large-Scale Optimization,” “Scenario Generation and Sampling,” and “Stochastic Integer Programming” in this encyclopedia.

INTRODUCTION

Computer and other technical systems are expected to be reliable during operation. However, their growing complexity, which is related to the intricate interdependencies among many heterogeneous components, makes the development of fault-free systems an unaffordable task in terms of time and cost. On the other hand, quality standards impose strict requirements on the reliability attributes and measures [1,2]. Fault-tolerance techniques are used to allow systems to continue their operations even in the presence of component failures, although in a possibly degraded mode. Hence, the quantification of the system reliability in combination with system performance is necessary.

Reliability can be evaluated using several approaches, generally classified into two categories: measurements-based and model-based [3]. Generally, the former is an attractive way to estimate the reliability of a system as it is based on real operational data. But it is costly and time consuming as it is based on real operational data collected from the system or a prototype. On the contrary, model-based approaches offer an abstraction of the real system, avoiding unnecessary details and system implementation. These models can be used to compute the reliability with

an acceptable approximation within affordable cost and time.

State-space models are often used because of their capacity of handling different failure/repair behaviors, such as imperfect coverage, correlated failures, and repair dependencies [3]. Continuous-time Markov chains (CTMCs) are state-space models commonly used for performance and reliability analysis. Homogeneous continuous-time Markov chains (HCTMCs) assume that the rates associated with events are time-independent and holding times exponentially distributed. Although HCTMCs are able to cover many cases, time-dependent rates and nonexponential distributions are also present in many real world situations [4,5]. In such cases, nonhomogeneous continuous-time Markov chains (NHCTMCs), semi-Markov processes (SMPs), Markov regenerative processes (MRGPs), or phase-type approximation can be used.

In order to show how to compute the reliability of a system based on a probabilistic model, consider the example of a *two-processor-parallel-redundant system with imperfect coverage*, adapted from Ref. 6. The system has two processors with the same time-independent failure rate and single repair facility with a certain repair rate. *Imperfect coverage* means that not all individual processor failures are recovered from. If a *covered failure* occurs in one of the two processors, the other one continues working and the system is up, although in a degraded mode. If a *not-covered failure* occurs, the system fails. Such a situation can be easily modeled by means of a HCTMC (see also the articles *Definition and Examples of DTMCs* and *Definition and Examples of CTMCs*). However, if we consider a time-dependent failure rate for the processors, the model is no longer homogeneous and the computation of the reliability becomes harder.

In the following, the reliability and related indices are formally defined; subsequently, we show how to compute them for the

mentioned example. In particular, three different techniques are presented: *piecewise constant approximation (PCA)*, *phase-type expansion*, and *discrete event simulation*. Finally, results obtained with these techniques are compared.

BASIC DEFINITIONS

Let X be a random variable representing the *time to failure* (TTF) (or *lifetime*) of a system. Such a random variable can be characterized by the cumulative distribution function (CDF), the probability density function (pdf), or the hazard rate function $h(t)$.

The CDF of the (non-negative) random variable X is simply defined as:

$$F_X(t) = P(X \leq t), \quad 0 < t < \infty \quad (1)$$

The pdf of X is defined by

$$f_X(t) = \frac{dF_X(t)}{dt} \quad (2)$$

The *hazard rate* (or *instantaneous failure rate*) is defined by

$$h(t) = \frac{f(t)}{1 - F_X(t)} \quad (3)$$

The *reliability* is defined by the Recommendation E.800 of the International Telecommunications Union (ITU-T) as the “ability of an item to perform a required function under given conditions for a given time interval.” Hence, for a time interval $(t_0, t_0 + t]$, the reliability $R(t|t_0)$ defines the probability that a system survives in this interval given that it was properly working at time t_0 .

If $t_0 = 0$, $R(t|0)$ defines the probability that a system is up until time t ,

$$R(t|0) = R(t) = P(X > t) = 1 - F_X(t) \quad (4)$$

The *conditional reliability* defines the probability that a system survives in the interval $(t_0, t_0 + t]$, given that the system has survived until time t_0 :

$$R_{t_0}(t) = \frac{R(t_0 + t)}{R(t_0)} \quad (5)$$

The expected life of a system is defined by the *mean time to failure* (MTTF) as:

$$E[X] = \int_0^\infty tf(t)dt = \int_0^\infty R(t)dt \quad (6)$$

The reliability represents the probability that a system is failure-free during a time interval. It is also useful to evaluate the probability of a system being failure-free at a precise instant of time. The *availability* is defined by ITU-T Recommendation E.800 as the “ability of an item to be in a state to perform a required function at a given instant of time or at any instant of time within a given time interval, assuming that the external resources, if required, are provided.”

Introducing the indicator random variable $I(t)$, which is equal to 1 when the system is up and 0 otherwise, we have the following definitions.

The *instantaneous availability* (or *point availability*) is the probability that a system is up at time t ,

$$A(t) = P(I(t) = 1) \quad (7)$$

Note that the instantaneous availability

$A(t)$ is always greater than or equal to the reliability

$R(t)$ and if the system has no repair or replacement strategies

$$A(t) = R(t).$$

The *steady-state availability* (or *limiting availability*) (A) is the value of $A(t)$ as t approaches infinity,

$$A = \lim_{t \rightarrow \infty} A(t) \quad (8)$$

Under very general conditions, the steady-state availability can be computed as:

$$A = \frac{\text{MTTF}}{\text{MTTF} + \text{MTTR}} \quad (9)$$

where the *mean time to repair* (MTTR) includes both the time to detect a failure and the time to repair it.

The *mean time between failures* (MTBF), instead, is the sum of MTTF and MTTR:

$$\text{MTBF} = \text{MTTF} + \text{MTTR} \quad (10)$$

The *interval availability* (or *average availability*) is the expected fraction of time the system is up in a given interval of time $(0, t]$. It is defined as

$$A_I(t) = \frac{1}{t} \int_0^t A(x) dx \quad (11)$$

It is easy to demonstrate that, when both limits exist:

$$A = \lim_{t \rightarrow \infty} A_I(t) = \lim_{t \rightarrow \infty} A(t) \quad (12)$$

For more details about the availability indices, modeling, and evaluation, see the article *Point and Interval Availability*.

Other indices have been defined for combining the performance and reliability/availability measure of a system, which is called *performability* [7]. As a matter of fact, fault-tolerant systems are able to continue providing service even in the presence of component failures, although in a degraded mode. Assuming that at the initial state the system is operating at its maximum performance, when a failure occurs, system performance may degrade. This kind of system offers several levels of performance.

Let S denote the set of all possible configurations in which the system can perform its activity, and let $\{X(t), t \geq 0\}$ on S define a continuous-time stochastic process describing the structure of the system at time t . Let $\pi_i(t)$ be the probability that the system is in state $i \in S$ at time t and π_i be the probability that the system is in state $i \in S$ as t approaches infinity. We can associate a *reward rate* to every state indicating the performance level offered by the system in that state. r_i represents the reward obtained per unit time spent in state $i \in S$.

The *reward rate at time t* is indicated as $Z(t) = r_{X(t)}$. It can be shown that [8] $L_i(t) = \int_0^t \pi_i(\tau) d\tau$ is the expected total amount of time spent by the system in state i during the interval $(0, t]$.

The *expected instantaneous reward rate* at time t is given by

$$E[Z(t)] = \sum_{i \in S} r_i \pi_i(t) \quad (13)$$

The *expected steady-state reward rate* of the system is

$$E[Z] = \lim_{t \rightarrow \infty} E[Z(t)] = \sum_{i \in S} r_i \pi_i \quad (14)$$

The *accumulated reward in $(0, t]$* represents the total amount of work performed by system during the interval $(0, t]$:

$$Y(t) = \int_0^t Z(t) dt \quad (15)$$

Then, the *expected accumulated reward in $(0, t]$* is the amount of work done by the system during the interval of time $(0, t]$:

$$\begin{aligned} E[Y(t)] &= E\left[\int_0^t Z(t) dt\right] = \int_0^t E[Z(t)] dt \\ &= \sum_{i \in S} r_i \int_0^t \pi_i(t) dt = \sum_{i \in S} r_i L_i(t) \end{aligned} \quad (16)$$

Figure 1, adapted from Ref. 7, presents an example of a Markov reward model (MRM) with three states. The reward rate is 2 for *State 1*, 1 for *State 2*, and 0 for *State 3*. $X(t)$ represents the state of the Markov chain at time t , and $Z(t)$ is the corresponding reward rate of the system. $Y(t)$ is the accumulated reward over the time interval $(0, t]$.

For a CTMC with one or more absorbing states, we can also compute the *expected accumulated reward till absorption*

$$\begin{aligned} E[Y(\infty)] &= \sum_{i \in S} r_i \int_0^\infty \pi_i(x) dx \\ &= \sum_{i \in S} r_i L_i(\infty) = \sum_{i \in S} r_i \tau_i \end{aligned} \quad (17)$$

where $\tau_i = L_i(\infty) = \lim_{t \rightarrow \infty} L_i(t)$ is the expected total time spent in state i before absorption [8].

Figure 1. Markov reward model, evolution of the system over time (X), reward rate (Z), accumulated reward rate (Y).

The *distribution of the accumulated reward till absorption* $P(Y(\infty) \leq y)$ can also be computed [9,10].

A SIMPLE EXAMPLE

In this section, we present in detail the above-mentioned system to show how to compute the reliability and performability indices described in the previous section.

Consider the *two-processor-parallel-redundant system with imperfect coverage* introduced earlier. Let P_1 and P_2 be the two processors; both of them have the same time-dependent failure rate $\lambda(t)$, which is not dependent on the state or the task of the processor. The coverage factor, denoted by c , represents the proportion of individual processor failures from which the system can automatically be recovered. Once P_1 (or P_2) fails, if the failure is covered by the recovery strategy, the system can properly work with only one processor, although with degraded performance, otherwise it fails.

The processor repair facility is characterized by a constant repair rate μ .

The system can be modeled by a Markov chain with three states (Fig. 2):

- *State 2.* both processors are properly working; the failure rate of each processor is $\lambda(t)$. Hence the equivalent failure rate of this state is $2\lambda(t)$. If a failure covered by the recovery strategy occurs (rate $2\lambda(t)c$), the system goes to *State 1*, otherwise to *State 0* (rate $2\lambda(t)(1-c)$);
- *State 1.* one processor failed because of a covered failure; the system can continue working in degraded mode with one processor. In this case, two possible scenarios are possible: the failed processor is repaired (with constant repair rate μ) before the working one fails, then the system goes back to *State 2*; or the working processor fails (rate $\lambda(t)$), and the system fails (*State 0*);

Figure 2. Two-processor-parallel-redundant system with imperfect coverage without (a) and with (b) repair.

- *State 0.* the system is down because either both processors failed or a non-recoverable failure occurred. This is an absorbing state (the system cannot be repaired, if this state is reached).

Note that in case there is no repair (Fig. 2a), the model is an NHCTMC. Since all rates are dependent on the same time-dependent function $\lambda(t)$, the time-dependent infinitesimal generator matrix can be factored into a time-independent matrix and a scalar function of time. Hence we can get the solution to the NHCTMC by solving a related HCTMC [8].

When repair from *State 1* back to *State 2* is introduced (Fig. 2b), we need to make two assumptions for the model to remain an NHCTMC:

1. Repair is minimal, that is, the repaired processor is in a state (age) equal to the one before its failure.
2. Repair time is negligible compared to time to failure.

The vector $\pi(t)$, whose i th element $\pi_i(t)$ is the probability that the system is in state i at time t , is equals to $[0 \ 0 \ 1]$ at $t = t_0$,

and the infinitesimal generator matrix is (see also the article **Definition and Examples of CTMCs**):

$$Q(t) = \begin{bmatrix} 0 & 0 & 0 \\ \lambda(t) & -\mu - \lambda(t) & \mu \\ 2\lambda(t)(1-c) & 2\lambda(t)c & -2\lambda(t) \end{bmatrix} \quad (18)$$

The failure rate $\lambda(t)$ is assumed to be the hazard rate of a two-parameter Weibull distribution:

$$\lambda(t) = \frac{\alpha}{\beta} \left(\frac{t}{\beta} \right)^{\alpha-1} \quad (19)$$

Table 1 shows the values of the parameters of the system. α and β are chosen to obtain a Weibull distribution with an increasing failure rate [11]; the rest of the parameters are typical values used to simplify computations.

We focus on the computation of the aforementioned *reliability* and *performability* indices for the described Markov model.

The transient behavior of a CTMC is defined by the Kolmogorov ordinary differential equations (ODE) system [12]:

$$\begin{aligned} \dot{\pi}(t) &= \pi(t)Q(t); \\ \sum_{i=1}^m \pi_i(t) &= 1 \end{aligned} \quad (20)$$

If $Q(t)$ is integrable, one solution exists and it is of the form $\pi(t) = \pi(t_0)\Phi(t, t_0) \cdot \Phi(t, t_0)$ can be evaluated using the Peano–Baker series [13] as:

$$\begin{aligned} \Phi(t, t_0) &= I + \int_{t_0}^t Q(\tau_1) d\tau_1 + \int_{t_0}^t Q(\tau_1) \int_{\tau_0}^{\tau_1} Q(\tau_2) d\tau_2 d\tau_1 \\ &\quad + \int_{t_0}^t Q(\tau_1) \int_{t_0}^{\tau_1} Q(\tau_2) \dots \int_{t_0}^{\tau_{h-1}} \\ &\quad Q(\tau_h) d\tau_h d\tau_{h-1} \dots d\tau_2 d\tau_1 + \dots \end{aligned} \quad (21)$$

However, the computation of $\Phi(t, t_0)$ for time-variant systems such as NHCTMCs is rather difficult. As a consequence, several methods have been proposed for the transient analysis of NHCTMCs as an alternative to

Table 1. Values of the parameters of the model.

Parameter	Value
α	2.1
β	1.02
μ	3.33×10^{-1} days
c	0.9
t_0	0

the ODE approach (see also the article *Transient Behavior of CTMCs*), such as PCA [14] and phase-type expansion (PH) [15].

The repair strategy of the system determines the method to use. Two different strategies have been considered [16]:

- *minimal repair* (or *as bad as before*);
- *maximal repair* (or *as good as new*), that is, the repaired processor behaves as a new one (with its age reset to zero).

In the first case, assuming that $\frac{1}{\mu} \ll \beta \Gamma(\frac{1}{\alpha} + 1)$ (MTTF of the Weibull distribution), that is, the recovery strategy is much faster than the inverse of the failure frequency, the model is an NHCTMC. Such a model requires only a *global clock* to describe all time-dependent transition rates as in every state, each component is as old as the system. To compute the reliability/performability of this model, PCA can be used.

In the case of maximal repair, instead, the system is non-Markovian as the transition rates from *State 2* to *State 1* and from *State 1* to *State 0* depend on how long the system has been in *State 2* or *State 1*, respectively. Furthermore, failure transition rate from *State 1* depends on the time spent by the nonfailed component in *States 2* and *1*. We note that for an SMP, all transition rates can depend on local time. In the current model with maximal repair, neither pure global clock nor pure local clock suffices. The model is neither an SMP nor an NHCTMC. However, using PH approximation, we can solve the problem.

For *performability* analysis, rewards are simply attached to the states of the Markov model by counting the number of active processors. In *State 2*, two processors are working, and hence, the reward rate is equal to

2; in *State 1*, where only one processor is working, the reward rate is 1. A reward rate equals to 0 is associated to the absorbing *State 0*. Hence, the reward rates are $r_2 = 2$, $r_1 = 1$, and $r_0 = 0$.

PIECEWISE CONSTANT APPROXIMATION

PCA is based on considering a time-variant function $f(t)$ as constant in certain intervals. Given the time interval $[0, t_0]$, it is divided into $n + 1$ shorter intervals of length δ : $t \in [0, t] \rightarrow t \in [i\delta, (i+1)\delta]$, $i = 0, 1, \dots, n$, where the function assumes the constant value $f(i\delta)$.

In the case of the failure rate $\lambda(t)$ of the considered Markov model:

$$\lambda(t) = \begin{cases} \lambda(\frac{\delta}{2}) & 0 \leq t < \delta \\ \lambda(\frac{\delta}{2} + \delta) & \delta \leq t < 2\delta \\ \vdots & \vdots \\ \lambda(\frac{\delta}{2} + i\delta) & i\delta \leq t < (i+1)\delta \\ \vdots & \vdots \end{cases}; i=0, 1, \dots, n \quad (22)$$

Figure 3 shows both the Weibull failure rate of the considered problem and its PCA with $\delta = 0.5$. With selected parameters of the Weibull function, the system has a monotonically increasing failure rate.

As a consequence of the failure rate approximation, also the infinitesimal generator matrix $Q(t)$ makes discrete changes:

$$Q(t) = \begin{cases} Q(\frac{\delta}{2}) & 0 \leq t < \delta \\ Q(\frac{\delta}{2} + \delta) & \delta \leq t < 2\delta \\ \vdots & \vdots \\ Q(\frac{\delta}{2} + i\delta) & i\delta \leq t < (i+1)\delta \\ \vdots & \vdots \end{cases}; i=0, 1, \dots, n \quad (23)$$

and the system is an HCTMC in each interval $[i\delta, (i+1)\delta]$, $i = 0, 1, \dots, n$. Hence, the transient behavior of the state probabilities can be computed as:

Figure 3. Comparison of the Weibull failure rate and its piecewise constant approximation.

$$\pi(t) = \begin{cases} \pi(0)e^{Q(\frac{\delta}{2})(t-0)} & 0 \leq t < \delta \\ \pi(0)e^{Q(\frac{\delta}{2}+\delta)(t-\delta)} & \delta \leq t < 2\delta \\ \vdots & \vdots \\ \pi(i\delta)e^{Q(\frac{\delta}{2}+i\delta)(t-i\delta)} & i\delta \leq t < (i+1)\delta \\ \vdots & \vdots \\ \vdots & \vdots \end{cases}; \quad (24)$$

$i = 0, 1, \dots, n$

where

$$\begin{aligned} \pi(\delta) &= \pi(0)e^{Q(\frac{\delta}{2})(\delta-0)} \\ \pi(2\delta) &= \pi(\delta)e^{Q(\frac{\delta}{2}+\delta)(2\delta-\delta)} \\ &\vdots \\ \pi(i\delta) &= \pi((i-1)\delta)e^{Q(\frac{\delta}{2}+(i-1)\delta)\delta} \\ &\vdots \end{aligned} \quad (25)$$

Reliability and performability indices for the *two-processor system* can be computed using SHARPE (Symbolic Hierarchical Automated Reliability and Performance Evaluator) [17], as shown in Fig. 4.

Since the model presents an absorbing state (*State 0*), that is, there is no repair strategy for the failure of the whole system, availability is not considered. Indeed, in this case, $A(t) = R(t)$.

Reliability

Since the CTMC has an absorbing state that represents the failed system (*State 0*), $\pi_0(t)$ is the probability that the system has failed at

or before time t ; the reliability can be simply computed as [8]:

$$R(t) = 1 - \pi_0(t) \quad (26)$$

Figure 5 shows the reliability of the considered system for different values of δ . We note that the two approximations are very similar.

Distribution Function

The CDF of the time to failure of the system is $F(t) = \pi_0(t)$ [8]. Figure 6 shows the $F(t)$ function of the considered system.

Probability Density Function

The *pdf* of the time to failure of the system is presented in Fig. 7. It is computed as $f(t) = \frac{d\pi_0(t)}{dt} = \lambda(t)\pi_1(t) + 2\lambda(t)(1-c)\pi_2(t)$ (see line 63 in Fig. 4 for the code).

Hazard Rate

The $h(t)$ is presented in Fig. 8. It is computed considering the state probabilities, as described in Ref. 18:

$$h(t) = \frac{\lambda(t)\pi_1(t) + 2\lambda(t)(1-c)\pi_2(t)}{\pi_1(t) + \pi_2(t)} \quad (27)$$

(see line 64 in Fig. 4). It has an increasing trend, but it is much less than the failure rate of each processor. Hence, the redundancy of processors and the recovery strategy are able to increase the reliability of the whole system.

Figure 4. Piecewise constant approximation—SHARPE code.

Mean Time to Failure

The MTTF of the considered system is 1.81 years. It is computed considering the approximate numerical solution of the integral $\int_0^\infty R(t)dt$ as the sum of the values of $R(t)$ in each time interval of length δ times δ itself (see lines 57, 80, and 96 in Fig. 4).

If we want to increase the average lifetime of the considered system without changing the number of processors of the system, we should

- use the processors with a smaller failure rate;
- improve the detection strategy to increase the coverage;
- improve the recovery strategy to increase the repair rate.

Expected Instantaneous Reward Rate

Figure 9 shows the expected instantaneous reward rate along time. It is computed in

Figure 5. Piecewise constant approximation—reliability.

Figure 6. Piecewise constant approximation—distribution function.

Figure 7. Piecewise constant approximation—probability density function.

Figure 8. Piecewise constant approximation—hazard rate.

Figure 9. Piecewise constant approximation—expected instantaneous reward rate.

SHARPE with the *exrt()* function (see line 65 in Fig. 4). The trend is very similar to the one of the reliability of the system, apart from the amplitude of the curve. Such a measure is very important in order to quantify the performance of the system in the presence of failure. For instance, suppose the reward rate being the Microprocessor without Interlocked Pipeline Stages (MIPS) of the processors and that it is required for the system to perform at least 0.5 MIPS. The expected instantaneous reward rate shows that after about 2.3 years, the system is no longer able to provide the desired service level. Hence, a renewal strategy is necessary.

Expected Accumulated Reward

The behavior of such an index is shown in Fig. 10 and it is computed in SHARPE by

summing the results of the *cexrt()* function in all the time intervals of length δ (see lines 56 and 66 in Fig. 4). The maximum value is 3.55, reached after about 4 years. Since the model has an absorbing state, the line $y = 3.55$ is an asymptote and this value represents the *expected accumulated reward till absorption*, that is, the expected reward accumulated by the system during its lifetime. Hence, if we consider again the reward rate being the MIPS, the maximum number of instructions the system is able to perform during the observation period $(0, 5]$ years is 1.12×10^{14} .

PHASE-TYPE EXPANSION

In order to present how the repair policy affects the reliability and performability of

Figure 10. Piecewise constant approximation—expected accumulated reward.

Figure 11. An alternative way for the representation of the system.

the system, now we consider the maximal repair policy. The failure times modeled by the Weibull distribution is approximated using the phase-type expansion technique [15]. Figure 11 shows an alternative way for the representation of the system that makes the description of the phase-type expansion technique simpler and emphasizes the different clocks of each processor. In this model, the failed component and the respective component failure rate are distinguished. For instance, if the system is in *State* (1, 1), both processors are up; in the *States* (0, 1) and (1, 0), one unique processor failed, P_1 and P_2 , respectively. Finally the *State* (0,0) is the absorbing state of the model, which represents that both processors failed, and thus the system failed as well.

The approximation of the Weibull distribution can be obtained using phase-type distributions. PH distributions are introduced in

Ref. 15 and have been widely used in stochastic modeling as they have different practical advantages: the Markovian properties, the closure properties, and the approximating properties. Many studies propose algorithms and numerical techniques for parameter fitting [11,19] and/or for comparing several approximations of nonexponential distributions, such as lognormal and Weibull. In Ref. 15 computation of reliability indices by means of PH distributions is discussed. In Ref. 20, the applicability of PH distributions for modeling the queuing networks is described. In Ref. 21, the authors compare several PH distributions, both continuous and discrete, and investigate which one best approximates a stochastic model.

A PH distribution is defined as the distribution of time to absorption of a CTMC with n transient states and one absorbing state (*State* $n+1$). The infinitesimal generator matrix Q of the CTMC can be partitioned as follows:

$$\begin{pmatrix} Q' & Q^0 \\ 0 & 0 \end{pmatrix} \quad (28)$$

where Q' is a $(n \times n)$ matrix that describes the transition rates between transient states of the CTMC, and Q^0 is the column vector of the transition rates to the absorbing state 0. The tuple $(\pi^{(0)}, Q')$ completely represents the PH distribution of order n , where $\pi^{(0)}$ is the $(n+1)$ initial probability vector. For the formal definition of PH distributions and

their properties, see the article *Phase-Type (PH) Distribution*.

The steps involved in PH expansion are: (i) the choice of stage combinations, for example, stages in series or parallel, and (ii) the derivation of the PH distribution parameters based on parameters of the original distribution. Depending on the approximated stochastic model, several stage combinations can be selected. In Ref. 22, some examples are provided. We use the n -stage-Erlang distribution. The stages are sequentially traversed, and the nonnegative continuous random variable represents the sum of the n independent exponentially distributed random variables with rate γ . Hence, the *pdf* of the resulting random variable X , which will be the approximation of the Weibull distribution, is the *pdf* of the n -stage-Erlang distribution:

$$f(x) = \frac{\gamma^n x^{n-1}}{(n-1)!} e^{-\gamma x} \quad (29)$$

Depending on the distribution to be approximated, different approaches can be used for evaluating the parameters of PH distribution (i.e., γ and n), such as moment matching [22], function fitting, and hybrid methods [11]. We will use the moment matching approach as it allows computing a closed-form expression for the failure rate γ and for the number of stages n as well:

$$\begin{aligned} m_1 &= \frac{n}{\gamma} \\ m_2 &= \frac{n(n+1)}{\gamma^2} \Rightarrow \gamma = \frac{m_1}{m_2 - m_1^2}, \quad n = \frac{m_1^2}{m_2 - m_1^2} \end{aligned} \quad (30)$$

Equalizing m_1 and m_2 to the first two moments of Weibull distribution,

$$m_1 = \beta \Gamma \left(1 + \frac{1}{\alpha} \right), \quad m_2 = \beta^2 \Gamma \left(1 + \frac{2}{\alpha} \right) \quad (31)$$

By substituting $\alpha = 2.1$ and $\beta = 1.02$ (Table 1) in the above formulas, we obtain $n = 4$ and $\gamma = 4.427$. If the computed value n is non-integer, it has to be rounded to the nearest integer. In this case, γ is to be recalculated accordingly.

Figure 12 shows the comparison of the Weibull *pdf* and the approximation obtained with PH expansion; the maximum error is 0.14. It is worth noting that, while selecting a proper stage combination, both the *pdf* and the *hazard rate* have to be checked. Figure 13 shows the comparison of the hazard rates. Since the hazard rates look quite different, it would be preferable to adopt a different stage combination in order to have a better approximation. However, the identification of the best PH approximation for the considered Weibull distribution is out of the scope of this article.

The system model resulting from using PH expansion is presented in Fig. 14. System states are represented specifying the number of phases for each processor. Hence, if the system is in *State (4, 4)*, both the components are up and they are at the stage 4. The failure of component P_1 is represented by *States (0, j)*, with $j = 1, \dots, 4$. The failure of component P_2 is represented by *States (i, 0)*, with $i = 1, \dots, 4$. *State (0, 0)* represents the system failure. A component failure, that is, the transitions from *States (1, j)* to *(0, j)*, or

Figure 12. Weibull pdf and its phase type approximation.

Figure 13. Weibull failure rate and its phase type approximation.

Figure 14. Phase type expansion of the system.

the transitions from *States* $(i, 1)$ to $(i, 0)$, can be covered with probability c . When a failure is not covered, the system fails [transitions from *States* $(i, 1)$ and $(1, j)$ to *State* $(0, 0)$]. When a component fails, it can be repaired or restored and becomes as good as new. This is represented by the transitions from *States* $(0, j)$ to *States* $(4, j)$ and by the transitions from *States* $(i, 0)$ to *States* $(i, 4)$.

An example of the SHARPE code for the specific example under analysis is shown in Fig. 15.

Reliability

The system reliability is computed as $R(t) = 1 - \pi_0(t)$ (Fig. 16). The reliability function is

computed using SHARPE (see line 165 in Fig. 15 for the code).

Cumulative Distribution Function

The *CDF* function is presented in Fig. 17. It is computed by means of SHARPE *tvalue()* function (see line 166 in Fig. 15).

Probability Density Function

Figure 18 presents the *pdf* of the time to failure computed with SHARPE (see line 167 in Fig. 15).

Hazard Rate

The failure rate is shown in Fig. 19. It is computed using the formula defined in the basic definitions section (see line 170 in Fig. 15).

Mean Time to Failure

The MTTF, or mean time to absorption, is using the *mean* function (see line 171 in Fig. 15): $\text{MTTF} = 4.39$ years.

Expected Instantaneous Reward Rate

This rate is computed by means of the *exrt()* function (see line 184 in Fig. 15). Figure 20 shows the trend of the expected reward rate at time t .

Expected Accumulated Reward

It is evaluated using the function *cexrt()* (see line 185 in Fig. 15) and plotted in Fig. 21.

The *expected accumulated reward till absorption* is: $E[Y(\infty)] = 8.66$.

Distribution of the Accumulated Reward till Absorption

The behavior of the distribution is shown in Fig. 22. The distribution of the accumulated

Figure 20. Phase type expansion—expected instantaneous reward rate.

Figure 21. Phase type expansion—expected accumulated reward.

Figure 22. Phase type expansion—distribution of the accumulated reward till absorption.

reward until absorption can be computed numerically using the SHARPE built-in function *rvalue()* (see line 188 in Fig. 15).

SIMULATION

The simulation is an alternative to analytic-numeric solution of models,

especially for large and complex models [23]. Although, it is possible to simulate the Markov model itself, we propose to compute reliability and performability indices of the considered system using stochastic reward nets (SRNs) [24] and to perform simulation by means of SPNP (Stochastic Petri Net Package) [25]. To model the *two-processor*

Figure 23. SRN representing the two-processor-parallel-redundant system with repair.

system with an SRN, the behavior of each processor is considered separately. Furthermore, the maximal repair policy (*as good as new*) is adopted. Figure 23 presents the SRN proposed to model the system described above. Let us consider the case of processor P_1 . At the beginning, it is properly working (place $p1w$). A failure can occur (transition $tp1$) leading the processor in a vanishing state (place $p1t$). If the failure is covered (transition $cp1$), the processor is to be repaired (place $p1r$). After repair (transition $rp1$), it works as good as when it was new (place $p1w$). If the failure is not covered (transition $up1$), the processor fails (place $fail$). The behavior of processor P_2 is the same.

Table 2 shows the rates and weights of the transitions.

Figure 24 presents the code to compute reliability and expected instantaneous reward rate in the SPNP software. The maximum number of simulation runs is 100,000, and the required confidence interval is 95% (see lines 22 and 24 of the code,

respectively). Reward functions $rel()$ and $rr()$ (lines 111 and 118 in Fig. 24, respectively) consider the system up if at least one processor is properly working (places $p1w$ and $p2w$) and no processor is failed (place $fail$). The reliability, the expected instantaneous reward rate, and the expected accumulated reward are presented in Figs 25, 26, and 27, respectively.

Mean Time to Failure

The MTTF, evaluated as mean time to absorption, is 4.62 years.

The *expected accumulated reward till absorption* is: $E[Y(\infty)] = 9.15$.

COMPARISON

The importance of the recovery strategy is evident considering the reliability computed with PCA and PH. As shown in Fig. 28, the reliability of the system with the maximal repair strategy, computed with PH expansion, is much greater than the one with minimal repair strategy computed with the PCA.

With minimal repair, the reliability becomes 0 after about 4.5 years, while after the same time reliability obtained with maximal repair is greater than 0.35. As a matter of fact, also the MTTF is much different. Maximal repair provides an average lifetime

Table 2. Rates and weights of the transitions.

Transition	Rate/weight
tp1, tp2	Weibull (α, β)
rp1, rp2	μ
cp1, cp2	c
up1, up2	$1 - c$

more than two times the one achieved when using an *as bad as before* repair strategy.

In the cases of PH expansion and simulation, the same recovery strategy is adopted. Figure 29 compares the reliability computed with the two techniques. Results obtained with PH expansion fall into the corresponding confidence intervals estimated with simulation when $t \leq 2.5$. Nevertheless, the trends of the reliability are very similar. Such a result is also confirmed by the mean times to failure.

REMANUFACTURING

GILVAN C. SOUZA
Kelley School of Business,
Indiana University,
Bloomington, Indiana

A supply chain is a network of facilities involved in the manufacturing and distribution of a product, involving procurement of raw materials, manufacturing of components, final assembly, storage in warehouses of distributors, and sales in retail stores or other distribution channels. The supply chain for beer, for example, includes procurement of beer ingredients such as yeast, barley, hops, and water; beer preparation through mixing and fermentation of ingredients; bottling, which could be done in a separate facility; shipment to national beer distributors, then to regional distributors, and finally to retail stores, where beer is sold. In supply chains, there are thus physical flows of raw materials, components, semifinished, and finished products; there are also financial flows, and information flows in the form of demand forecasts, inventory positions at different storage points, and other information. For more information on supply chains. The physical flows in a traditional supply chain are mostly unidirectional, from raw materials producers through manufacturers, distributors, and then to consumers. These are called *forward* flows.

In reverse supply chains, the flows of products are in the opposite direction, from consumers to producers. As an example, the reverse supply chain for beer cans involves collection of used beer cans, consolidation in intermediate storage points, and shipment to aluminum producers and/or recyclers. The term *closed-loop supply chain* (CLSC) indicates a supply chain where there is a combination of forward and reverse flows, such that these two types of flows may impact each other, and may thus require some level of coordination.

An example of CLSC is shown in Fig. 1. Pitney Bowes is an Original Equipment

Manufacturer (OEM) based in Stamford, Connecticut, which manufactures mailing equipment that matches customized documents to envelopes, weighs the parcel, prints the postage, and sorts mail by zip code. Pitney Bowes leases about 90% of its new product manufacturing, and sells the remainder. A typical leasing contract is for 4 years, and a typical life cycle for a Pitney Bowes product is 6 years. At the end of a leasing contract, customers may upgrade to newer generation equipment if available. If that is the case, the customer returns the used equipment to Pitney Bowes, which tests and evaluates the condition of the used machine, and makes a *disposition* decision: scrap for materials recovery (recycling), which is done for the worst quality returns; dismantle for spare parts harvesting, which is done for medium quality returns; or remanufacturing, which is done for the best quality returns so as to reduce remanufacturing cost. Remanufacturing consists of bringing the used product to a common operating and aesthetic standard, often with upgrades in some of the product's functions. More details on the remanufacturing planning process at Pitney Bowes can be found in Ref. 1. Remanufactured products are then sold as a cheaper alternative to new products. Note how the forward and reverse flows impact each other: customers may opt for either remanufactured or new products, depending on respective price levels, and perceived quality of the remanufactured product by the customer. Further, lease or sales of new products impact the flow of available used products for remanufacturing in the future. The CLSC for Pitney Bowes thus requires coordination between the forward and reverse flows.

It is important to distinguish the types of product returns in CLSCs, and the available disposition decisions for product returns. There are three types of product returns in CLSCs:

- *Consumer Returns.* These are lightly used products, most of which are not

Figure 1. An example of a closed-loop supply chain with remanufacturing.

defective, which are returned to retailers (and then to manufacturers) by consumers as a result of liberal return policies. Typical reasons for returns include: buyer remorse, a better price elsewhere, a product that does not meet performance expectations, or technical complexity. Consumer returns account for 5–6% of personal computer sales, and up to 35% for fashion products.

- *End-of-Use Returns.* These are illustrated in the Pitney Bowes case above. Contrary to consumer returns, end-of-use returns have been extensively used by customers, their quality level is more variable depending on usage patterns, and thus remanufacturing here is a more extensive operation.
- *End-of-Life Returns.* These returns have reached the end of their useful life; their quality condition is poor and materials and/or part recovery are common disposition options.

In addition to landfilling—an option that is illegal for some products in some jurisdictions (e.g., electronic equipment cannot be landfilled in some US states such as California, Maine, Massachusetts, and Minnesota)—disposition decisions for product returns include:

- *Incineration.* Incineration reduces the amount of solid waste going to landfills—a significant issue for countries with limited landfill space—and it may be an attractive option for products or materials where recycling is difficult or uneconomical. In addition, incineration is commonly used for energy recovery. For example, Denmark incinerates 58% of its municipal solid waste toward energy recovery [2]. On the other hand, incineration increases the amount of toxic emissions such as mercury, and is therefore regulated.
- *Recycling.* Recycling means material recovery, and it is an attractive option for products where returns have little economic value due to technological obsolescence (e.g., old computers), or are in poor quality condition (e.g., product returns heavily damaged during transportation). Recycling can be mandated by regulation: in the Netherlands, 85% of the weight of each car at the end of its life needs to be recycled (as opposed to landfilled or incinerated); for electronic equipment, the current mandated recycling target is about 65% in the European Union. See introductory articles *Recycling* and *Take-Back Legislation and*

Its Impact on Closed-Loop Supply Chains.

- *Parts Harvesting.* Here, the firm recovers selected parts from a product return for use in warranty and service contracts. When the part is subject to wear and tear, as is common in mechanical components, this option is viable if the product has been lightly used such as consumer returns. Otherwise, for electronic components, this is a common disposition option. Fleischmann *et al.* [3] estimate that IBM can save as much as 80% per part by dismantling product returns relative to procuring the part from a supplier.
- *Remanufacturing.* This is a value-added operation as illustrated in the Pitney Bowes case above, and it can be the most profitable disposition decision. The economic viability of remanufacturing depends on several factors: the existence of a product core that retains significant value after usage (e.g., engine block), the existence of a market for remanufactured products, which is related to customers' acceptance of remanufactured products, total remanufacturing, and reverse logistics costs (collection, transportation, testing, labor and parts), among other factors.
- *Resale (As-Is).* This can happen if a secondary market for the used product exists, such as is the case with used cars, and some standard IT equipment.

Remanufacturing has the potential for higher profitability among the disposition decisions; it is thus the focus of this article. In new item manufacturing, materials and components are completely homogeneous. In used item remanufacturing, on the other hand, the key inputs—product returns, also called *cores*—are uncertain in quality, timing, and quantity. Product returns thus need to be graded according to their quality; returns with worse quality consume more capacity (more labor and equipment hours) and cost more to remanufacture than better quality returns. The uncertainty with respect

to timing and quantity can be minimized through proactive acquisition strategies, such as controlling the price paid for product returns [4]. We show subsequently, how operations research can be used for production planning with remanufacturing: the quantities of each type of product return that should be remanufactured, disposed of, or harvested for parts in each period.

Remanufacturing also offers another challenge on *remarketing*. It is often the case that remanufactured products are perceived as inferior to new products; as a result they are priced lower than their equivalent new counterparts. Hauser and Lund [5] report 35–55% average price discounts for remanufactured products relative to equivalent new products in industries such as automotive parts, compressors, machinery, office furniture, toner cartridges and the like. Similarly, Subramanian and Subramanyam [6] report price discounts for remanufactured products relative to new products, with the same warranty, ranging from 15% for consumer electronics to 40% for video game consoles at eBay. The key decisions in remarketing are pricing and distribution (channels of distribution) for remanufactured products relative to new products so as to maximize the firm's profitability, considering potential cannibalization of sales between new and remanufactured products. We present a model in the section titled "Pricing of Remanufactured versus New Products" that illustrates how this decision can be made.

Besides remarketing and production planning, there are many other decisions that need to be made in CLSCs. Like in regular forward chains, remanufacturing decisions in CLSCs can be classified into strategic, tactical, and operational decisions. We illustrate some of these decisions in Table 1, and offer further references in that table for readers interested in those particular topics.

PRICING OF REMANUFACTURED VERSUS NEW PRODUCTS

In this section, we show how operations research and economic models can be used to study the strategic interaction between

Table 1. Strategic, Tactical and Operational Decisions in Remanufacturing with Some References

Type of Decision	Time Frame	Examples
Strategic	Several years	• How should the reverse supply chain be designed? Specifically, where are the locations of collection sites, consolidation sites, remanufacturing, and recycling sites? [7–13] • Should an Original Equipment Manufacturer (OEM) remanufacture? If so, what should be the prices of remanufactured products? [14–16]) • Should the firm lease or sell its products?
Tactical	Several months	• Product acquisition for remanufacturing: how many returns should be procured, at which quality level, and at which price? [4,17–19] • Production planning for remanufacturing: how many returns of each type (quality grade) should be remanufactured and disposed of in each period? [1,20,21]
Operational	Hours/days	• How should the different remanufacturing operations be scheduled at the shop? [22] • Disassembly planning: what is the sequence and depth of disassembly? [23]

remanufactured and new products; the models provide recommendations regarding pricing of remanufactured and new products to maximize a firm’s profitability. We consider a specific business setting; however, the basic modeling setup can be extended to study other settings. Specifically, we consider a monopolist firm that sells (new) products, which have a useful life (to the consumer) of one period. For example, for photocopiers, a period would be, say, 5 years, after which it can no longer be used productively by the consumer.

To keep the exposition simple, we consider a time horizon of two periods, and use subscript i to indicate period $i, i = 1, 2$. In period 1, the firm only sells new products. Consumers who buy a new product in period 1 have a used product at the beginning of period 2. If a consumer has a used product at the beginning of period 2, and decides to buy another new product, she *can* return her used product to the firm “for free” (e.g., consumers can return old computers to Dell for free upon purchase of a new Dell computer). The firm *can* use these used products recovered from the consumers, for remanufacturing. Like new products, remanufactured products also have a useful life of one period; one can thus think of remanufacturing as extending the product’s useful life to another

period. For example, for a copier, remanufacturing would consist of replacing worn out parts, performing cosmetic repairs, such as removing scratches (which may involve replacing parts), and upgrading some modules to the latest technology. Assume that the firm collects, in period 2, a fraction $\rho < 1$ of all used products in the market (i.e., those sold in period 1), which it can remanufacture. The remaining fraction $(1 - \rho)$ is destroyed or kept by consumers (say, in their garages) and does not interfere in period 2’s market.

Thus, at the beginning of period 2, any consumer (regardless of whether she has a used product or not) has three choices: (i) she buys another new product, (ii) she buys a remanufactured product, or (iii) she does not buy anything. Remanufactured products are labeled as such, and sold at a discount relative to the new product; the firm would like to know which price would maximize its profitability. The basic argument for engaging in remanufacturing in this case is to reach customers who believe that the new product’s price is too high and thus do not buy it; remanufacturing thus allows the firm to expand its customer base and increase revenues. Although consumers prefer new to remanufactured products, a low enough price of the remanufactured product may provide enough of an incentive for them

to buy remanufactured products instead of new, causing *cannibalization*; too much cannibalization can be detrimental to profitability because the new product commands higher margins. We now provide a simple modeling framework to study this problem.

A key characteristic of the model is modeling consumer behavior. For a given product, different consumers have different willingness-to-pay (the maximum amount they are willing to pay) for the new product, which we denote by θ . For example, some consumers have little use for a photocopier, and therefore would not be willing to pay much for it. In this case, their willingness-to-pay for the copier is near zero. On the other hand, some consumers (e.g., law firms) make extensive use of photocopiers, and therefore are willing to pay a significant amount for a copier that meets their needs, say \$10,000. Between these two extremes, are most consumers: one can model the consumer base by assuming a willingness-to-pay for the new product for a random consumer to be between 0 and 10,000. To eliminate parameters in the model, the minimum willingness-to-pay (in this case, near zero), and the maximum willingness-to-pay (in this case 10,000) are normalized to 0 and 1, respectively. A common assumption on the way that consumers distribute between the two extremes is to assume a uniform distribution of consumer types: every willingness-to-pay θ for the new product between 0 and 1 is equally as likely. We denote this by $\theta \sim U[0, 1]$. A uniform distribution for willingness-to-pay implies a downward sloping, linear demand curve. To see this, denote the price of the new product in the first period by p_{n1} , $0 < p_{n1} < 1$. Then, all consumers with willingness-to-pay $\theta > p_{n1}$ derive a positive utility (defined as willingness-to-pay minus price) for the new product; given that the potential market size is normalized to 1, the quantity of new products sold is given by $q_{n1} = 1 - \Pr\{\theta > p_{n1}\} = 1 - p_{n1}$. A key assumption made here is that consumers are not *strategic*, that is, they are not able to anticipate a future presence of a remanufactured product in the second period (or a potentially lower price for the new product) when making a first period purchasing decision.

In the second period, the monopolist offers both new and remanufactured products. Again, given that any product purchased in the first period reached its useful life, all consumers in the market are again looking to buy a new or remanufactured product in the second period. As discussed in the introduction, consumers typically view remanufactured products as inferior relative to new products; this is modeled by considering that a consumer that is willing to pay θ for the new product is also willing to pay $\delta\theta$ for the remanufactured product, where $0 \leq \delta \leq 1$. If $\delta = 0$, the consumer does not consider the remanufactured price as a substitute, regardless of price. This could be the case, for example, for certain medical supplies that have contact with blood; consumers may perceive them as unsafe, even after sterilization. If $\delta = 1$, remanufactured and new products are perfect substitutes; a common example is toner cartridges—most consumers see no difference between remanufactured and new cartridges. Most markets fall in between these two extremes, with $0 < \delta < 1$: consumers prefer the new over the remanufactured product if they have the same price. To derive the quantities sold for new and remanufactured products, we consider that a consumer chooses the product that gives him/her the maximum utility. So, consider a remanufactured product priced at $p_{r2} < p_{n2}$. A customer of type $\theta < p_{n2}$ has negative utility for the new product; his/her utility for the remanufactured product is $\delta\theta - p_{r2}$, which is positive if $\theta > p_{r2}/\delta$. A customer of type $\theta > p_{n2}$, however, has positive utilities for both products but for $\theta > (p_{n2} - p_{r2})/(1 - \delta)$, the utility of the new product is higher than for the remanufactured product (this threshold can be found by solving $\theta - p_{n2} > \delta\theta - p_{r2}$ for θ). As a result, the quantity of new products sold in the second period is $q_{n2} = 1 - (p_{n2} - p_{r2})/(1 - \delta)$ (this comprises all customers who have a higher utility for the new product), whereas the quantity of remanufactured products sold is $q_{r2} = (p_{n2} - p_{r2})/(1 - \delta) - p_{r2}/\delta$ [this comprises all customers who have a higher (positive) utility for the remanufactured product]. With this basic interaction modeled, the firm can solve

an optimization problem to find the optimal prices of remanufactured and new products.

Assume that the variable production cost for the new product in the first period, new product in the second period, and remanufactured product are c_{n1} , c_{n2} , and $c_r < \min\{c_{n1}, c_{n2}\}$, respectively. The firm solves the following optimization problem:

$$\begin{aligned} \max_{p_{n1}, p_{n2}, p_r} \quad & \Pi = q_{n1}(p_{n1} - c_{n1}) + q_{n2}(p_{n2} - c_{n2}) \\ & + q_{r2}(p_{r2} - c_r), \end{aligned} \quad (1)$$

$$\text{s.t. } q_{r2} \leq \rho q_{n1}, \quad (2)$$

$$q_{r2}, q_{n1}, q_{n2} \geq 0, \quad (3)$$

where as shown above, $q_{n1} = 1 - p_{n1}$, $q_{n2} = 1 - (p_{n2} - p_{r2})/(1 - \delta)$, and $q_{r2} = (p_{n2} - p_{r2})/(1 - \delta) - p_{r2}/\delta$.

Equation (1) is the total profit across period; the terms represent, respectively, profit from the first period, new and remanufactured products from the second period. Constraint (2) indicates that the number of remanufactured products cannot exceed the number of available used products sold in the first period (i.e., this is a used products availability constraint). Finally, constraints (3) are logical constraints that ensure that the prices chosen do not result in nonnegative quantities. The nonlinear optimization problem (Eqs 1–3) can be solved analytically or numerically (see **Foundations of Constrained Optimization**); the analytical solution is not as straightforward as it results in multiple “regions,” such that the optimal prices are dependent on different combinations of the cost and δ parameters. In general, the firm remanufactures if $c_r < \delta c_{n2}$. For more detailed analyses the reader is referred to Refs 1 and 15 and references therein.

Finally, we note that the model above is deterministic: demand is a deterministic function of prices, and the quantity of returns is a deterministic function of previous sales. This is standard in higher-level strategic modeling of CLSCs, given the period length under consideration (the product’s useful life). Uncertainty clearly exists at a more tactical level (e.g., monthly demand for remanufactured products or number of

returns received or procured in a given week). Strategic models of CLSCs, however, consider longer periods of time (one period comprises several years in this case), and as a result there are several reasons why uncertainty is not included in models:

(i) there is less uncertainty in the data when it is aggregated over longer periods of time (e.g., for a stable product, yearly demand is less uncertain than monthly demand, and so forth); (ii) there is less to be gained in modeling the system at that level of detail, considering the decision variables of interest here (prices); and finally (iii) these models are not meant to be decision support models, but rather provide broader insights (e.g., under which conditions should a firm remanufacture.)

PRODUCTION PLANNING FOR REMANUFACTURED PRODUCTS

We now describe how production planning for remanufacturing is different from production planning for new products, and how operations research (specifically linear programming; see articles in the section titled “Linear Programming (LP)” in this encyclopedia) can help a planner decide on the optimal production plan. As discussed in the introduction, the basic difference is that the basic material input for remanufacturing—cores or returns—are not homogeneous; there are differences in their quality and availability during the planning horizon. A good quality return demands less processing capacity from the facility, and costs less to remanufacture than a bad quality return. If the firm has excess returns in a given period, it can salvage them (for example, by selling to a recycler, or dismantling for spare parts). We present a rather simple model for illustration; for more information on the environments faced by remanufacturing firms. Refs 1, 20, and 21 provide a more comprehensive coverage in the use of operations research models for production planning in remanufacturing.

Our simple model is meant to represent an *aggregate* production plan, where the planner decides upon the overall remanufacturing quantities for a given product family

(e.g., Motorola cell phones), as opposed to individual product models (e.g., the models V750, Razr2, and E8 by Motorola). Our model assumes that there are demand forecasts D_t for the family of remanufactured products under consideration for each period t in the planning horizon, and forecasts B_{it} for returns of each quality i for each period t in the planning horizon. There are mechanisms for forecasting the total quantity of returns received in each period (denoted by $B_{\bullet t} = \sum_i B_{it}$); this is reasonably straightforward if the firm leases its new item production (i.e., $B_{\bullet t}$ would be the number of expiring leases in period t), otherwise time series methods such as triple exponential smoothing can be used (see **Holt–Winters Exponential Smoothing**). Given $B_{\bullet t}$, an estimate of B_{it} would be $B_{it} = q_i B_{\bullet t}$, where q_i is the historic average proportion of returns of quality i . We introduce our complete notation below.

INDEXES

- i quality, $i = 1$ (best), $\dots, I$ (worse)
 t time period, $t = 1, \dots, T$

PARAMETERS

- D_t Demand forecast for remanufactured products at period t
 B_{it} Quantity of returns of quality i at period t
 s_i Unit salvage value for returns of quality i that are not remanufactured
 h_i Unit holding cost for return of quality i
 h_r Unit holding cost for remanufactured product
 b Unit backlogging cost
 c_i Unit remanufacturing cost for return of quality i
 a_i Unit capacity usage by return of quality i
 K_t Total capacity available at time t

DECISION VARIABLES

- z_{it} Quantity of quality i returns remanufactured in period t

- v_{it} Quantity of quality i returns salvaged in period t
 y_t^+ Inventory of remanufactured products at the end of period t
 y_t^- Backlog of remanufactured products at the end of period t
 u_{it} Inventory of quality i returns at the end of period t

The remanufacturing problem can be formulated as a linear program (LP) as follows:

$$\min TC = \sum_{t=1}^T \sum_{i=1}^I \{c_i z_{it} - s_i v_{it} + h_i u_{it}\} + h_r y_t^+ + b y_t^-, \quad (4)$$

$$\text{s.t. } (y_{t-1}^+ - y_{t-1}^-) + \sum_i z_{it} - (y_t^+ - y_t^-) = D_t, \quad t = 1, \dots, T; \quad (5)$$

$$z_{it} + u_{it} - u_{i,t-1} + v_{it} = B_{it}, \quad i = 1, \dots, I; \quad t = 1, \dots, T; \quad (6)$$

$$\sum_i a_i z_{it} \leq K_t \quad t = 1, \dots, T; \quad (7)$$

$$z_{it}, u_{it}, v_{it}, y_t^+, y_t^- \geq 0, \quad i = 1, \dots, I; \quad t = 1, \dots, T. \quad (8)$$

The objective function in Equation (4) minimizes total costs, comprising variable production cost, salvage cost (note the negative sign for the salvage revenue), holding cost for returns, holding cost for remanufactured products, and backlogging cost. The set of constraints (5) represents the inventory balance equations for remanufactured products: for each period t , beginning inventory net of backlogs ($y_{t-1}^+ - y_{t-1}^-$) plus remanufacturing production ($\sum_i z_{it}$) minus demand (D_t) is equal to ending inventory net of backlogs $y_t^+ - y_t^-$. The set of constraints (6) represents the inventory balance equations for returns according to quality level: for each quality i and time period t , beginning inventory ($u_{i,t-1}$) plus returns received (B_{it}) minus quantity remanufactured (z_{it}) minus quantity salvaged (v_{it}) equals ending inventory u_{it} . The set (7) represents the capacity constraints for each period. Finally, the set (8) represents the nonnegativity constraints.

Our model does not incorporate fixed costs for remanufacturing in a period (also called as *setup costs*) because remanufacturing is for the most part a labor intensive operation, not requiring elaborate machine setups; our model is also targeted at the family level, where setup costs are less of a concern.

The problems (4–8) can be solved numerically to find the optimal production plan. Ferguson *et al.* [1] show that if there are no capacity constraints (i.e., K_t is large enough for all t), then the firm always remanufactures the exact quantity demanded in each period if $h_r > h_i$. That is, the ending inventory of remanufactured products y_t^+ is always zero in each period. In essence, the firm carries inventory of remanufactured products only in situations where there are large demand spikes (i.e., D_t is large for some t) coupled with the inability of meeting the exact demand in each period due to capacity constraints.

One other point to make is that the formulation above assumes away any uncertainty in demand or returns; in practice both are likely to occur. There are two ways to deal with this problem. First, the firm may carry some safety stock of remanufactured products to protect against uncertainty. For example, one can multiply all values of D_t by $(1 + z \cdot \sigma)$, where z is a safety factor, and σ is the standard deviation of the ratio actual demand-to-forecast (A_t/D_t). This is clearly a heuristic, but one that is easy to implement and use in practice. Second, the firm solves the problem (Eqs 4–8) in a *rolling horizon* basis: start at the beginning of the planning horizon (period 1), solve the problem, and implement the first-period solution (z_{i1}, v_{i1}). At the end of period 1, after *actual* demand A_1 and return quantities are realized, the firm updates the inventory positions and demand forecasts, and re-solves the problem for the planning horizon 2, 3, ..., $T + 1$; this process continues each period. By using a rolling horizon approach coupled with some level of safety stock, the firm protects itself against forecast error. This is a *heuristic* solution to the problem with demand uncertainty; an optimal solution would require the formulation of Equations (4–8) as a stochastic program, where demand and return scenarios, with their associated probabilities, are

considered in the problem (see *Modeling Uncertainty in Optimization Problems*).

CONCLUSION

This article provides an introduction to applications of operations research to remanufacturing. We first introduce basic terminology, such as the different types of returns, different types of disposition decisions available in CLSCs, and the basic differences between remanufacturing and regular manufacturing. In essence, the basic input to remanufacturing operations—product returns or cores—are not homogeneous, as they arrive to the facility in different quality conditions, and at a timing and quantity that is more difficult to control than raw materials and parts in new item manufacturing. Second, remanufactured products are typically perceived as inferior to new products, even when sold with the same warranty and are thus priced at a lower price point; remanufactured products can thus be used to reach new customer segments, such as customers who wouldn't be able to afford the new product, however, remanufactured products can also cannibalize on the sales of new products (which typically have higher profit margins). We provide an example of how economic modeling and nonlinear programming can be used to answer the basic question: given a certain cost structure, and level of market acceptance for remanufactured products, should a firm offer a remanufactured product in addition to its new product? If so, what are the respective prices that maximize profitability? Further references on this issue include Refs 14–16.

An important strategic decision for a firm that engages or is considering engaging in remanufacturing is the overall design of a CLSC. Issues such as location of facilities (collection points, aggregation points, remanufacturing facilities, etc.) and optimization of flows in this network have been addressed through large-scale mathematical programming techniques, typically mixed-integer programming models [7–13].

At a more tactical level, the firm must implement a remanufacturing plan to meet demand for remanufactured products. First,

the firm must carefully plan the acquisition of product returns; this includes procuring an amount that takes into account the variable quality (and as a result, variable cost and yield) of returns. Research [17,18] has addressed this problem using variants of the classical newsvendor model (see **News vendor Models**), or economic modeling of supply and demand curves [4,17]. Given a forecast of returns (with their qualities) and demand for remanufactured products, the firm can use mathematical programming techniques (linear programming, stochastic programming) to provide the optimal production plan that minimizes the cost of meeting demand; we have provided a simple example of such problems but there are other approaches (see survey in Ref. 21).

Finally, at a more operational level, the firm must decide on the sequence and depth of disassembly of returns; these problems have been studied using mixed-integer linear programming models and graph theory (see survey in Ref. 23). It must also sequence the remanufacturing operations in the shop floor. Given the complexity of different shop configurations and bills of materials, these problems are more specific to each firm, and have been mostly addressed through simulation [22].

Given the introductory nature of this article, we have been able to only offer a glimpse of operations research applied to the study of CLSCs. We have provided several references for further study; many of these are reference books. For an overview of operations research and economic tools applied to CLSCs at a more advanced level, but still contained within 25 printed pages, the reader is referred to Ref. 24.

RENDEZVOUS SEARCH GAMES

STEVE ALPERN
Department of Mathematics,
London School of
Economics, London, UK

INTRODUCTION

Rendezvous search games arise in a very natural way from the general theory of search [1,2], if one simply assumes that the “hidden object” that the searcher wishes to find is another searcher who wants to be found. That is, rendezvous search is a common-interest game where both players want to minimize the expected time required for them to meet. These games may also be seen as search extensions of the one-shot coordination problems of Schelling [3], who asked where two parachutists should agree to meet after they are randomly scattered by the winds. The difference is that Schelling’s problem simply ends in failure if they do not meet at once, whereas in rendezvous search (as in all search problems) they continue to try to find each other until they meet. Schelling emphasized the importance of focal points in his problem, whereas in rendezvous search focal points are (usually) eliminated by symmetry. Rendezvous problems are faced quite commonly when individuals become separated, or when their specification of a meeting point is insufficient. They have been faced by convoys of ships at sea, scattered by a storm. They are faced by migratory birds dispersed during migration, and by parent penguins who go fishing and then have to find their offspring in large colonies. Computers solving problems in a parallel fashion have to use rendezvous protocols to regularly check the progress of the other processor. Rendezvous protocols when on dangerous patrols are discussed by McNab [4], and popular accounts have been given in the press [5].

The *rendezvous search problem* was first posed by Alpern [6] at the end of a 1976 talk on zero-sum (hide and seek) games, as

a cooperative contrast to those games (which are discussed in Shmuel Gal’s article *Search Games* in this volume). In the basic form of rendezvous search, two players are placed according to a known joint distribution (usually independently) in a known search region Q . They know their own location, but only up to some symmetry of Q . So, for example, if Q is a circle, they know nothing of use even about their own location (unless Q is labeled or directed). If Q is a disk, they would know their distance from the center. [These notions of spatial symmetry are discussed at length in Ref. 7 (and in Ref. 8) in terms of the corresponding subgroup of the symmetries of Q , but we shall treat symmetries informally here.] Each player moves with unit speed until the first time T when their distance is less than a prescribed “search radius,” which is taken to be zero when Q is a network. The minimum value of the expected meeting time $\hat{T}$ that the players can achieve is called the *rendezvous value* of Q , denoted $R = R(Q)$, and the corresponding strategies are called *optimal*. Note that $R(Q)$ depends crucially on which of certain symmetry assumptions are made, as discussed below.

There are two main forms of the problem determined by whether or not we can distinguish between the two players, a different kind of symmetry. In the *asymmetric* (or player-asymmetric) form of the game, the players can use distinct pure strategies. So, in asymmetric rendezvous one particular strategy pair that is always available is what we term wait for mommy (WFM), where Player I (Mommy) searches Q exhaustively to minimize the time taken to find a randomly placed stationary object, and Player II (Baby) simply waits. In fact, this is usually a good strategy (pair), but rarely an optimal one. If we cannot distinguish between the players and are (for example) writing a note in a hiker’s manual telling them what to do if they get separated, then we are restricted to suggesting a single strategy for both players to adopt. This is called the *symmetric* (or player-symmetric) form of the game. In this

form, optimal strategies are usually mixed (randomized). To see why pure strategies may not be useful, consider the case where Q is an infinite line and the players start a known fixed distance apart, and they are each initially faced in a random direction. If they happen to face the same direction (which has probability one-half) and they follow the same pure strategy, they will never meet. Hence, the expected meeting time of any doubly adopted pure strategy is infinite. The rendezvous values for the player-asymmetric and symmetric version are denoted, respectively, by $R^a(Q)$ and $R^s(Q)$.

The original formulation of the continuous rendezvous search problem, including a rigorous definition of the rendezvous value, is given in Alpern [8]. A survey of the field, covering most developments up to 2002, is given in Alpern [9]. A full treatment of rendezvous theory, considered as part of the field of search games, is given in the monograph of Alpern and Gal [10]. Here we will refer to the original publications.

This article is organized as follows. The section titled “Two Original Examples” describes the two original rendezvous problems posed in the 1976 talk, and subsequent results toward their solution. The section titled “Rendezvous on the Line” discusses rendezvous on the infinite line, when the players have information about the distribution of the distance, but not the direction, to their partner. The section titled “Uncertain Initial Conditions” deals with rendezvous on the line, for the case where the distribution of initial distance is not known. It seeks rendezvous strategies for which the expected meeting time is small with respect to the mean of the distance distribution. The section titled “Rendezvous in Higher Dimensions” covers rendezvous in higher dimensions. The section titled “Miscellaneous Rendezvous Problems” deals with other versions of rendezvous, including a brief description of how rendezvous problems are studied in the theoretical computer science literature.

TWO ORIGINAL EXAMPLES

To illustrate the flavor of specific rendezvous problems, we describe briefly the two

problems given in the original presentation of rendezvous search [6]. These were posed as perhaps a good starting point for the theory, as they were simple and presumably easy to solve. Surprisingly, neither is fully solved to this day.

In this section, we present the two problems and then give a summary of the work that has been done on them. Later sections will present the bulk of the literature on rendezvous theory, mostly in areas not foreseen in the original talk (some of these areas were suggested in Ref. 8).

Highly Symmetrical Regions

The first problem seeks to avoid the focal points of Schelling [3] by choosing the search region Q with maximal symmetry (a transitive symmetry group, so *no* distinguished points).

Problem 1 [Astronaut Problem]. *Two astronauts land independently and uniformly on large, smooth spherical body Q . The body does not have a fixed orientation in space, nor does it have an axis of rotation, so that no common notion of position or direction is available to the astronauts for coordination. Given unit walking speeds for both astronauts, how should they move about so as to minimize the expected meeting time $\hat{T}$ (before they come within the detection radius)?*

This two-dimensional (sphere) problem is still unsolved. The one-dimensional analog, the circle Q , has been extensively studied (see Table 1). There are six versions, depending on the assumptions we make regarding player symmetry and spatial symmetry. The three types of spatial symmetry are (i) a labeled circle, say a clockface; (ii) a directed circle; (iii) an undirected circle. The four strategies suggested for these in the initial paper of Alpern [8] where such symmetry notions were defined formally in terms of group theory are as follows: FOCAL (go to a specified point like 3 o'clock); OP-DIR (the two players go in opposite directions); COHATO (coin half tour: repeatedly go half way around, choosing direction equiprobably); WFM (the wait-for-mommy strategy discussed above). Of course,

Table 1. Conjectured Best Strategies for Circle (Circumference 1)

Players	Labeled Circle	Directed Circle	Undirected Circle
Symmetric	FOCAL, $\hat{T} = \frac{1}{3}$	COHATO, $\hat{T} = \frac{3}{4}$	COHATO, $\hat{T} = \frac{3}{4}$
Asymmetric	OP-DIR, $\hat{T} = \frac{1}{4}$	OP-DIR, $\hat{T} = \frac{1}{4}$	WFM, $\hat{T} = \frac{1}{2}$

not all of these are feasible for all versions. The conjectured optimal strategies for the six versions are given below, followed by their corresponding expected meeting times $\hat{T}$. It is perhaps an easy but useful exercise for the reader to check these times.

We note that, although it is an open question as to whether COHATO is indeed optimal in the two versions for which it is suggested, it has been shown that in the other four cases the suggested strategy is indeed optimal. For a class of initial distributions which includes the uniform, it was shown by Alpern [11] that OP-DIR is optimal for asymmetric rendezvous on the directed circle, extending the similar result of Howard [12] for the uniform distribution. Howard obtained this result by first establishing that OP-DIR is optimal for the labeled circle and then used the following argument. First note that rendezvous values (minimum of $\hat{T}$) can only increase (weakly) as we go to the right in the table, as the players have less information. Since OP-DIR is optimal for the labeled circle and feasible for the directed circle, it must also be optimal for the directed circle. Howard [12] also established that WFM is optimal for asymmetric rendezvous on the undirected circle. The optimality of the FOCAL strategy for symmetric rendezvous on the labeled circle was established by Alpern [13]. As a matter of curiosity, we note that COHATO is optimal for both players in the zero-sum search game on the circle (spatial symmetry is irrelevant in this context), for the case where one of the players wants to *maximize* T . So some might find this conjecture strange.

Rendezvous on Discrete Locations

Rendezvous games are mainly about continuous movement of players within a region but, as with similar games, discrete approximations are often very interesting. The second

problem posed in the original talk (sometimes known as the *telephone coordination problem*, or *rendezvous on the complete graph K_n*), can be stated as follows.

Problem 2 [Mozart Café Problem]. *Two friends agree to meet for lunch at the Mozart Café in Vienna on the 1st of January 2000. However, on arriving at Vienna airport, they are told there are three (or n) cafés with that name, no two close enough to visit in the same day. So, every day each can go to one of them, hoping to find his friend there. This is a player-symmetric problem, so what is the best randomized strategy for both to adopt?*

For general n , this problem is still open. When $n = 2$ it is not too difficult to show that the players cannot do better than choose a random café each day [14,15]. The Crawford–Haller result [15] is about strategy coordination with revealed information about previously chosen strategies, but for $n = 2$ the other player’s strategy is revealed as being the other café (unless you meet), so the two formulations are equivalent. Anderson and Weber [14] showed that in the player-asymmetric version, the optimal strategy pair is WFM, with say friend I searching all n cafés in random order, and friend II picking a random one and going there every day. Anderson and Weber introduced an important class of strategies (which we call AW_n) for the symmetric problem: Assuming you do not meet on the first day, do the following in every group of $n - 1$ days thereafter. With probability p_n , visit the remaining $n - 1$ cafés in random order; with probability $1 - p_n$, stay where you are (they calculated the optimal values of p_n). It has been conjectured that AW_n is indeed optimal. After some small progress [16,17] toward showing that AW_n has certain approximate optimality properties, in 2006 (after 30 years!) Richard Weber [18] used

semidefinite programming techniques to make the breakthrough of establishing that AW_3 is indeed optimal for $n = 3$, one of the outstanding results in rendezvous theory. Subsequently his PhD student J. Fan [19] has partially extended his techniques to related problems, including cases where the cafés are so large that the friends might not meet even if they go to the same one (i.e., there is a positive *overlooking probability*).

RENDEZVOUS ON THE LINE

The general formulation of rendezvous games given in Ref. 8 assumes that the search region Q is compact, but in fact the region that has been most studied is the infinite line. The two players are initially placed a distance d apart, and faced in random directions. The distance d may be fixed or chosen randomly from a given cumulative distribution function F . The player-asymmetric version has been solved for the cases where F is a point distribution or is convex on a bounded domain $[0, D]$. On the other hand, the player-symmetric version is still unsolved, and the progress that has been made in bounding the rendezvous value R^s in the case where d is known rests largely on numerical techniques.

Player-Asymmetric Version

In this version, a strategy for say Player I is a function $f(t)$, which represents his net forward motion at time t , where forward is the direction he is initially facing. Thus, f must satisfy the conditions $f(0) = 0$ and $|f(t) - f(t')| \leq |t - t'|$ (unit speed condition). It was shown by Alpern and Gal [20] that the optimal strategy pair for known d is a variation on WFM, which we call modified WFM. If player I plays Mommy, her optimal strategy is simply to go at unit speed a distance d in one direction (say forward) and then $2d$ in the other, finding Baby (player II) equiprobably at times d or $3d$, with mean meeting time $\hat{T} = 2d$. Suppose Baby (player II) does not just wait, but instead plays his optimal response. Clearly, this is to move in some direction for time $d/2$, hoping to meet Mommy at time $d/2$ (with probability $1/4$). If this fails, the best he can do is return to

his starting point at time d (again hoping Mommy will arrive there at time d , probability $1/4$). Failing this, he knows that Mommy went in the direction away from him and is now at distance $2d$ from him. So he moves in some direction (say forward) for the next time period of length d (meeting at time $2d$ with probability $1/4$). Finally, he returns to his start at time $3d$ where he will meet Mommy at last (unconditional probability $1/4$). This is the modified WFM strategy (pair), which has $\hat{T} = (1/4)(d/2 + d + 2d + 3d) = \frac{13}{8}d = R^a$.

It was shown by Alpern and Howard [21] that this problem is equivalent to the following *alternating search* problem (not a rendezvous problem): There are two searchers, each at the center of an interval of length d . There is an object hidden equiprobably at the four ends of the two intervals. The two searchers can move *one at a time* (hence the term *alternating*). What strategy for the searchers minimizes the expected time to find the object? Clearly, the searchers first alternate in going distance $d/2$ to one of the ends on their line, and then alternate in going distance d to the other end. Thus the same set of equiprobable times occurs, $\{d/2, d, 2d, 3d\}$. An easy way to solve more complicated problems of this type, without using dynamic programming, is given in Ref. 21. This alternating search theory was subsequently adapted by Alpern and Beck [22] to prove that the modified WFM strategy (taking steps which are multiples of $D/2$, where D is the maximum of d) is optimal when the distribution of d is convex on $[0, D]$, with $R^a = (4\mu + 9D)/8$. In particular, for the uniform distribution of d on $[0, D]$, $R^a = 11/8$.

A natural question to ask is whether waiting (staying still on a nontrivial time interval) is ever optimal. This was answered in the negative by Gal [23], who showed that there is no distribution F for which WFM is an optimal strategy. Alpern and Beck [22] strengthened this to show that in any optimal strategy (for any F) there is a nontrivial time interval on which both players are moving with (the maximum) speed 1. Note, however, that these negative results for waiting hold only for the line, as Howard [12] has shown that waiting may be optimal on the circle (as mentioned above). These

negative results for the line also require the assumption that both players have the same maximum speed. If Player I has maximum speed 1 but Player II has lower maximum speed $v < 1$, then it was shown by Alpern and Gal [24] That, for fixed $d = 1$, if v is less than the golden mean $\frac{\sqrt{5}-1}{2} \doteq .61803$, then Player II should stay still for time 1, and then move at maximum speed in a certain way, and the rendezvous value is $(v^2 + 4v + 2) / (v + 1)^2$. If v exceeds the golden mean, then a modification of the optimal strategy for $v = 1$ given above is optimal, and the rendezvous value is $(4v^2 + 7v + 2) / (v + 1)^3$.

Player-Symmetric Version

As noted above, the symmetric version of rendezvous on the line requires mixed (or behavioral) strategies. This problem was originally proposed in Ref. 8, where the following strategy 1F2B (one forwards, two backwards) was suggested (where μ and D denote the mean and maximum of the initial distance d): If the maximum distance is D , do the following in every time interval of length $3D/2$: (i) pick a random direction to call forward; (ii) go forward for time $D/2$; (iii) go backward for time D . Note that, if the players pick the same forwards direction, they will be at their initial distance apart again at time $3D/2$; otherwise, they will have met. The expected meeting time $\hat{T}$ for 1F2B satisfies the equation

$$\hat{T} = \frac{1}{4}(\mu/2) + \frac{1}{4}(D + \mu/2) + \frac{1}{2}(3D/2 + \hat{T}),$$

or

$$\hat{T} = \frac{1}{2}\mu + 2D.$$

In particular, for an initial distance of $d = 1$ (where $D = \mu = 1$), this gives the bound $R^s \leq 2.5$. This estimate has been improved a number of times, by Anderson and Essegaiier [25], Baston [26], Uthaisombut [27], Alpern [28], and Han *et al.* [29]. The last group have the best published estimates of R^s (normalizing to $d = 1$ as usual) for the line, of $2.076 \leq R^s \leq 2.1287$, which they obtained using absorbing Markov chain theory, fractional quadratic programming, and semidefinite programming.

It is an open question whether giving the players a common sense of direction on the

infinite line helps them at all in the player-symmetric version of rendezvous. It is conjectured that it does not help. (It certainly does help in the player-asymmetric version, as it reduces the problem to the celebrated linear search problem; see Ref. 20.)

The Labeled Interval

Rendezvous on the line has also been studied in the version where the points are labeled, for the case of the unit interval $Q = [0, 1]$. This project was initiated by Howard [12]. Players are initially placed independently according to a common distribution F . Howard showed that, if F has a nondecreasing density, then an optimal strategy for the asymmetric (and hence for the symmetric version) is for the players to go right until they meet the *right sweeper* (an imaginary agent whose location at time t is given by $1 - t$) and then to stick with him. In the case of the uniform distribution, another optimal strategy is simply to go to the middle of the interval and wait. Howard's results for the interval have been extended by Chester and Tutuncu [30] and Alpern [13]. Note that, in this setting, a strategy for a player is of the form $f_x(t)$: that is, it tells him where to be at every time t if his initial position is x . Howard's strategy given above has the property that, if $f_x(t) = f_{x'}(t)$ for some t , then $f_x(s) = f_{x'}(s)$ for all $s \geq t$. We call such strategies *sticky*. Alpern [13] studied analogous rendezvous problems on labeled networks and showed that for the symmetric version there is always an optimal strategy which is sticky, and also gave an example of a network for which there is a unique optimal strategy pair for the asymmetric problem, and it is not sticky. It is worth observing that, for symmetric rendezvous problems on *labeled* networks (including the labeled interval), pure strategies are sufficient for optimality.

Other Rendezvous Problems on the Line

There are several other versions of the rendezvous problem that have mainly been attacked when the search region is the line. We describe them briefly here.

Bounded Resources. Alpern and Beck [31,32] proposed the problem where the players have a limited amount of fuel (or stamina), so that Player I can travel a total distance (formally, *total variation*) of a and Player II a total distance of b , with $a \geq b$. The asymmetry of their resources means that we consider the player-asymmetric version and, as usual, they are placed a fixed distance d apart and faced in random directions. Of course, if $b = 0$, this is just the well known *linear search problem* of Bellman [33] and Beck [34]. The condition under which they can ensure a meeting is that $5a + 3b \geq 15d$ and in this case [31] when $d = 1$, the rendezvous value (least expected meeting time) $R_{a,b}$ is given by

$$R_{a,b} = \begin{cases} (31 - 5a - 3b)/8 & \text{if } 2a + b \leq 6 \\ (19 - a - b)/8 & \text{if } 2a + b \geq 6 \text{ and } a \leq 3 \\ (16 - b)/8 & \text{if } b \leq 3 \leq a \\ 13/8 & \text{if } 3 \leq b. \end{cases}$$

On the other hand, if $5a + 3b \geq 15d$, they cannot guarantee a meeting, so the best they can do is to maximize the probability of a meeting. For the case where $d = 1$ is known, this maximum probability $P_{a,b}$ is given by Alpern and Beck [32]

$$P_{a,b} = \begin{cases} 0 & \text{if } a + b < 1 \\ 1/4 & \text{if } a + b/3 < 1 \leq a + b \\ 1/2 & \text{if } a/3 + b/3 < 1 \leq a + b/3 \\ 3/4 & \text{if } a/3 + b/5 < 1 \leq a/3 + b/3 \\ 1 & \text{if } 1 \leq a/3 + b/5. \end{cases}$$

Similar results are given when the initial distance distribution is uniform, triangular, and negative exponential.

Multirendezvous. Thus far we have been considering the rendezvous of *two* players on the line. We now consider the problem where n players are placed randomly at consecutive integer locations on the line, faced in random directions, and wish to minimize the time $T_{n,m}$ taken for m of them to be at the same location. We call these problems $\Gamma_{n,m}^a$ and $\Gamma_{n,m}^s$, with respective rendezvous values $R_{n,m}^a$ and $R_{n,m}^s$ for the player-asymmetric and player-symmetric versions. Our previous

results concern the special case $n = m = 2$. The minimax time for all n of them to meet will be denoted M_n , considered in the player-asymmetric version. Note that, when $m > 2$, we must analyze information transfer between two players who meet.

The first of these problems to be studied was $\Gamma_{3,2}^a$. Optimal strategies move in time intervals of $1/2$ between adjacent half integers ($k/2$), and such strategies can be specified by indicating the integers k for which a player changes direction at time $k/2$. We give this list in vector form, so $x_i = 1$ if the player changes direction at time $i/2$ and $x_i = 0$ otherwise. So, for example, the vector $[1, 1, 1, \dots]$ indicates a strategy which always changes direction. Using a branch and bound method, the game $\Gamma_{3,2}^a$ was solved by Lim *et al.* [35], who showed that $R_{3,2}^a = 47/48$. Up to permutations of the labels of the players, there are six optimal strategy profiles, which we give in the $[]$ notation below:

$$\begin{aligned} & \{[0, 1, 0, 0], [1, 0, 0, 1], [1, 0, 1, 0]\}, \\ & \{[0, 1, 0, 0], [1, 0, 0, 0], [1, 0, 1, 0]\}, \\ & \{[0, 1, 0, 0], [1, 0, 0, 0], [1, 1, 0, 1]\}, \\ & \{[1, 1, 0, 1], [1, 0, 0, 0], [1, 1, 0, 1]\}, \\ & \{[0, 1, 0, 0], [1, 0, 0, 0], [1, 1, 1, 1]\}, \\ & \{[0, 1, 0, 0], [1, 0, 0, 1], [1, 1, 1, 1]\}. \end{aligned}$$

For large values of $m = n$, both rendezvous values are asymptotic to $n/2$, as shown by the following estimates of [35]:

$$\frac{n}{2} \leq R_{n,n}^a \leq R_{n,n}^s \leq \frac{n}{2} + 5.$$

Since $m = n > 2$, players will sometimes meet with another before the end of the game. We call the part of the game before a player's first meeting *Stage I* and the part after this meeting *Stage II*. The strategy that gives the upper bound is defined as follows (the word *start* refers to a player's initial position):

- *Rule 1 (overriding everything else).* If someone you meet says "follow me," then follow him (adopt same path).
- *Stage I.* Pick a random direction, independently and equiprobably each time.

Go a distance $1/2$ in that direction and then return to start. Then go a distance $1/2$ in the opposite direction and return to start. This takes total time 2, and you are back at start at integer times. Repeat until you are back at start and have met another player. (This return to start can occur at time 1 or at time 2.) Then proceed to Stage II.

- *Stage II.* Go at speed 1 a maximum distance 1 in the direction away from that in which you met another player earlier (in Stage I). If you meet another player in this time (after time $1/2$ or time 1 from beginning of the stage), then return immediately to your start and wait. If after time 1 you have not met another player, then proceed to Stage III.
- *Stage III.* Proceed at unit speed toward and then past your start, continuing until the game ends, instructing everyone you meet to follow you. (If two players in Stage III meet, then their groups together contain all the players, so the game is over.)

A related result of Alpern [9] for the multirendezvous of n players initially placed at unit distances along a circle of circumference n shows that the expected meeting time $R_{n,n}^s(C)$ has the upper bound $R_{n,n}^s(C) \leq 2^{n-2}/(2^{n-1}-1) + n/2$. To break symmetry, the associated strategy involves each player picking a random number in $[0, 1]$ at the outset, and using it to determine which player is the leader when two meet.

The minimax rendezvous problem, that of evaluating minimax time M_n for all the players to meet, was introduced by Lim and Alpern [36] (in the player-asymmetric form—in the symmetric form no maximum time can be guaranteed). The case $n = 2$ is the usual rendezvous problem in minimax form, and the expected time minimizing strategy (modified WFM), with maximum time 3, is also minimax. Simple WFM is also minimax. Thus $M_2 = 3$. The minimax strategy found by Baston [26] for $n = 3$ is more complicated. It establishes (together with an estimate from Ref. 36) that $M_3 = 3.5$. Baston's strategy was shown to be the unique optimal strategy by Alpern and Lim

[37]. Lim and Alpern [36] showed that, for large numbers of players, the minimax value M_n is asymptotic to $n/2$, which is the full information meeting time. Gal [23] established the upper bound

$$M_n \leq n/2 + 2 \log_2 n + 3.5.$$

An interesting aspect of Baston's strategy is that, sometimes when two players meet, they adopt different future paths (split up). If players who meet must stay together (sticky rendezvous), we denote the minimax time by $\tilde{M}_n$. It turns out that this is indeed a severe restriction, as it is shown in Ref. 36 that $\tilde{M}_3 = 5$. This contrasts with Alpern's result [13] that, for symmetric rendezvous on labeled networks, there is always an optimal (expected time minimizing) strategy which is sticky.

UNCERTAIN INITIAL CONDITIONS

In this section we deal with the question of how the rendezvousers on the line should proceed when there is uncertainty about the distribution function F of their initial distance. This question was vaguely suggested as one of the seven *questions for further work* in Ref. 8 as "Adversary-rendezvous games: Suppose the two searchers' initial position in Q is chosen by another player who wishes to maximize their meeting time." The question was first attacked by Baston and Gal [38], who presented a number of strategies which work well against arbitrary initial distributions F , in the sense that the expected meeting time against F is small with respect to the mean of F . One of their estimates was improved by Alpern and Beck [39].

Asymmetric Rendezvous

The first result in Baston and Gal [38] concerns the asymmetric rendezvous problem on the line. They showed that there exists an asymmetric pair of pure strategies such that the expected meeting time against any distribution F is at most 5.73μ , where μ is the mean of F .

Subsequently, Alpern and Beck [39] considered the following *alternating* strategy

(the players alternate reversing directions): In each time period n both players move in a fixed direction at maximum speed 1. At the end of each period, exactly one of the rendezvousers reverses direction, and they reverse in alternating periods. There is no first period; periods go $\dots, -3, -2, -1, 0, 1, 2, \dots$. Each period has length exactly $\hat{a}$ times the length of the previous period, where

$$\hat{a} = \frac{1}{3} + \frac{2^{2/3}}{3(8 + \sqrt{62})^{1/3}} + \frac{2^{1/3}(8 + \sqrt{62})^{1/3}}{3} \approx 1.5994.$$

If this strategy pair is used against any distribution F , the expected meeting time is at most $V\mu$, where

$$V = \frac{1}{2} + (1/8) \left(\frac{8}{\hat{a} - 1} + 7 + 5\hat{a} + 3\hat{a}^2 + \hat{a}^3 \right) \approx 5.514,$$

where μ is the mean of F . This result is sharp in that no other alternating strategy does better.

Note that, against a known distribution F , there is no need for the players in an asymmetric problem to randomize—pure strategies are sufficient. However, against an unknown F , the players are essentially playing a zero-sum game against Nature (who chooses F). In this case, it is well known that randomization may help. In the asymmetric rendezvous context, they may pick their *pair* of strategies randomly, which means their individual strategies will be correlated. The best estimate for this version of the problem is given in Ref. 38, Theorem 4.1, where the authors exhibit a probability distribution over pairs of distinct rendezvous strategies, so that if this “correlated” strategy is used against any distribution F , the expected meeting time is at most 4.42μ .

Symmetric Rendezvous

We now consider the scenario where the two players are constrained to use the same mixed strategy. The first result for this case is [38, Theorem 5.1], that there

exists a mixed search strategy $\bar{v}$ which, if adopted with independent randomization by the two players against any distribution F , gives an expected meeting time at most $(7 + 2\sqrt{10})\mu \approx 13.33\mu$.

The rendezvousers can improve this bound by using joint randomization. Here, S, S^* , and $(S^*)^*$, respectively, denote pure strategies, mixed strategies, and probability distributions over mixed strategies. Baston and Gal showed for this case that there exists a probability distribution $\bar{v}$ over mixed search strategies which has the following property: If a mixed strategy is chosen according to the distribution $\bar{v}$ and then adopted by both players with independent randomization, then the expected meeting time against any initial distance distribution $F \in \mathcal{F}$ is at most 11.4μ , where μ is the mean of F .

RENDEZVOUS IN HIGHER DIMENSIONS

Although one of the original problems in rendezvous theory (the “Astronaut Problem,” Problem 1 of the section titled “Highly Symmetrical Regions”) involves a two-dimensional search region, most of the theory has been developed for one-dimensional regions. Rendezvous on the plane was first attacked by Thomas and Hulme [40], who simulated the problem of a loud, fast helicopter seeking a slow, quiet walker. Their simulations indicate that (p. 48)

... there may be an advantage in role reversal. The helicopter should try to drag the walker toward it. Thus it should search less and make its presence audible more and eventually stay within a small area waiting to the walker to rendezvous with it

Planar Rendezvous, Diagonal Start

The first formal model for player-asymmetric planar rendezvous was developed by Anderson and Fekete [41]. They first considered the assumption that the players had a common sense of direction (each has a compass). In this case, as shown earlier [20] for the line, the problem can be reduced to a single-player search problem: minimize the expected time to find a stationary target

hidden uniformly on a circle of known radius. However, they then considered a true rendezvous problem by assuming no common sense of direction (no compasses). They take the search region as the integer grid on the plane ($\mathbb{Z} \times \mathbb{Z}$), with their initial vector difference taken equiprobably from the set $\{(1, 1), (1, -1), (-1, -1), (-1, 1)\}$: that is, they are on opposite vertices of a unit square. (We call this diagonal start.) Each player is faced in a random direction, which he calls N (North). They prove that the optimal (expected time minimizing) strategy pair is the *A-F strategy* $[(N, W, S, S, E, E, N, N), (N, S, N, S, N, S, N, S)]$. Note that A-F can be seen as a modified WFM strategy, with Player I doing a time minimizing exhaustive search (with meeting times 2, 4, 6, 8) and Player II at his start at these times but moving away at odd times in the hope of decreasing the meeting time by 1. Alpern and Baston [42] showed that, if there is a common sense of clockwise, there is another distinct optimal strategy pair, namely the *A-B strategy* $[(N, E, S, W, S, W, N, E), (N, S, E, S, W, N, E, N)]$. They also showed that, if there is no common sense of clockwise, then all optimal strategies are *generalized A-F strategies* (as defined below) and these strategies are also uniformly optimal (maximize probability of meeting by time t for all t).

Definition 1 [Generalized A-F Strategies]. A strategy pair is called *generalized A-F* if one player goes around the square $(\pm 1, \pm 1)$ (with respect to his start) in a cyclic fashion, while the other is back at his start at even times and away at odd times.

Parallel Start, $n \geq 2$

The Anderson-Fekete model [41] can be extended to n dimensions by initially placing the players on even nodes (those with even sum of coordinates) of the integer lattice $\mathbb{Z}^n$. In particular, Alpern and Baston [43] considered the case where the difference between the players is of length 2 and parallel to one of the coordinate axes. Let R_n denote the rendezvous value, assuming no common

sense of direction, and even *no common sense of clockwise*. They show that $R_2 = 197/32$ (extending the earlier result of Alpern and Gal [20] that $R_1 = 13/4$). However, unlike the diagonal start problem of Anderson and Fekete, none of the optimal strategies is uniformly optimal. Furthermore, for general n they show that

$$R_n \leq \frac{32n^3 + 12n^2 - 2n - 3}{12n^2} \rightarrow \frac{8}{3}.$$

In a related article, Alpern and Baston [44] showed that when the players *do have a common sense of clockwise*, it helps them, reducing the rendezvous time from $197/32 \approx 6.1563$ to $194/32 \approx 6.0625$. Also, unlike the lack of uniform optimality in the no-common-clockwise version [44], there exist uniformly optimal strategies.

Multiagent versions of planar rendezvous have been analysed by Lin *et al.* [45, 46]. They give strategies (which may or may not depend on a common clock) that ensure that the players will eventually all meet.

A related paper of Alpern [47] considered the problem faced by players who want to rendezvous in Manhattan and can see each other when they are on a common street or avenue. More work is needed on this “line of sight” version of rendezvous for other regions.

MISCELLANEOUS RENDEZVOUS PROBLEMS

In this section we discuss some other variations on the basic rendezvous problem.

Rendezvous-Evasion Games

We now consider a zero-sum win-lose game proposed by the author, in which the common aim of two rendezvouchers R_1 and R_2 is to meet strictly before either of them encounters an enemy searcher S (who has the opposite aim). This game models the situation, for example, where a rescuer R_2 is sent to find a downed mobile pilot R_1 before the enemy on the ground S finds him. The search region is the complete graph K_n , and the three agents start at distinct nodes at time 1. The value v_n of the game is therefore the probability of the searcher winning, with best play on both sides.

Asymmetric Rendezvous-Evasion on K_n . Lim [48] showed that $v_3 = 47/76$. The optimal strategies are described as follows. Each agent P labels his initial position as $P(1)$, his next *new* positions as $P(2)$, $P(3)$, and so on. When going to a new position, he can only move randomly (equiprobably) among the locations not already visited. The optimal mixed strategy for the rendezvous team is as follows: At Step 1, R_1 moves to location $R_1(2)$, while R_2 stays at location $R_2(1)$. Before they separate, they jointly choose $i = 1, 2, 3$ with probabilities $(7/19, 6/19, 6/19)$ and then: if $i = 1$, R_1 visits location $R_1(3)$ (uniquely determined), R_2 stays at $R_2(1)$; if $i = 2$, R_1 returns to $R_1(1)$; R_2 visits $R_2(2)$; if $i = 3$, R_1 stays at $R_1(2)$; R_2 visits $R_2(2)$. At this point, they have a common labeling of the locations and hence meet equiprobably at one of them at the next step. The searcher begins by moving to a new location $S(2)$. Then, he picks $j = 1, 2, 3$ with probabilities $(5/19, 5/19, 9/19)$ and goes to location $S(j)$. For steps $k > 3$, he visits each location with probability $1/3$.

Lim also gives a strategy for the searcher which guarantees him a win on K_4 with probability $31/54$. She further shows that, when all the agents have a common circular ordering of the locations (but may move between any two), this knowledge helps the rendezvouchers and the value is $\left((1 - 2/n)^{n-1} + 1\right)/2$.

Symmetric Rendezvous-Evasion on K_3 . In the symmetric version of rendezvous-evasion studied by Lim and Alpern [36], the two rendezvouchers must be given the same mixed strategy to follow. Unlike the asymmetric version in the previous section, the rendezvouchers cannot be certain to have met by a given time, so we require the rendezvous team to meet within a given time bound, namely by step 3.

We assume that all agents have a common notion of clockwise direction around the three nodes, which we view as vertices of a triangle. This assumption allows the agents to label their initial location as 0, and the remaining two as 1 and 2 in a clockwise direction from 0. In this notation, there are

nine pure strategies:

$$\{(0, 0), (1, 2), (2, 1), (0, 1), (1, 0), (2, 2), (0, 2), (1, 1), (2, 0)\}.$$

We will be concerned with four distributions over these strategies, which we call behavioral strategies.

$$b^1 = \frac{1}{3} (1, 1, 1, 0, 0, 0, 0, 0, 0),$$

$$b^2 = \frac{1}{3} (0, 0, 0, 1, 1, 1, 0, 0, 0),$$

$$b^3 = \frac{1}{3} (0, 0, 0, 0, 0, 0, 1, 1, 1),$$

$$b^4 = \frac{1}{9} (1, 1, 1, 1, 1, 1, 1, 1, 1).$$

Alpern and Lim [49] showed that the value of the common-direction, two-step, symmetric rendezvous-evasion game on K_3 is $57/81$. The optimal strategy for the rendezvouchers is for each of them to use (the same) behavioral strategies b^i , $i = 1, 2, 3$, equiprobably. The optimal strategy for the searcher is to use the random strategy b^4 .

The interpretation of the rendezvous strategy is as follows: The controller broadcasts a number $1, 2, 3$, equiprobably, which only the rendezvouchers receive. When number i is broadcast (and received), both rendezvouchers adopt the behavioral strategy b^i . The need for mixtures over behavioral strategies is unusual in game theory. Such strategies were introduced in Ref. 50.

Alpern and Lim [49] also found that, in the version with no common notion of direction, the value lies in the interval $[58/81, 59/81]$.

Uncertain Motives of “hider”

Sometimes when a person is lost, it is uncertain to the searcher whether or not the lost person wants to be found. For example, a missing teenager might be a “runaway”; a fictional Russian submarine in *The Hunt for Red October* by Clancy [51] might be lost or might be defecting. If p denotes the probability that the lost agent wants to be found, we obtain a class of games that connects a zero sum search game (in the sense of Gal’s article **Allocation Games** in this volume) to a rendezvous problem. Alpern and Gal [24] solved problems of this type when the search

region is a tree or the infinite line, and Gal and Howard [52] considered discrete locations. An opportunity for further study is the situation where *both* agents have unknown motives.

Information Transfer, Search Costs

In the basic form of rendezvous search, the players receive no additional information (other than that they have not yet met) until they meet. This assumption has been relaxed by Baston and Gal [53], who allowed each player to leave a mark at his starting point which the other player could see if he arrived there. They considered the complete graph and the line as search spaces. Baston and Kikuta (unpublished) have also worked in this area. Alpern [28] supposed that rendezvousers on the line get some information at certain stages in the game.

Another assumption of rendezvous is that search, for example, at a discrete location, is costless. This is unusual in search theory. The effect of including such costs has been studied by Kikuta and Ruckle [54].

Theoretical Computer Science

This volume is concerned with Operations Research, but we feel we should at least give a brief mention to a very vibrant area of rendezvous research in the theoretical computer science literature. See, for example, Refs 55–59.

RENEWAL FUNCTION AND RENEWAL-TYPE EQUATIONS

LIQIANG LIU
EURANDOM, Eindhoven University of
Technology, Eindhoven, Netherlands

THE RENEWAL FUNCTION

Consider a renewal process $\{N(t), t \geq 0\}$ where $N(t)$ counts the number of occurrences of a certain event up to time t . The points in time distinguished by the event, called *renewal epochs*, are denoted, chronologically, by random variables $S_1, S_2, \dots$. The difference between any two successive members of this sequence is called *interrenewal time*. By the definition of renewal process, the interrenewal times are mutually independent and have a common distribution F . Throughout this article we assume the renewal process is pure, that is, the distribution of S_1 is independent and also follows F .

Definition 1 [Renewal Function]. The renewal function $M(\cdot)$ is defined as

$$M(t) = \mathbb{E}(N(t)), \quad t \geq 0. \quad (1)$$

The renewal function $M(\cdot)$ can be directly computed from its definition as follows:

$$M(t) = \sum_{n=1}^{\infty} n \mathbb{P}(N(t) = n) = \sum_{n=1}^{\infty} \mathbb{P}(N(t) \geq n).$$

Notice the following equivalence of events

$$N(t) \geq n, \text{ if and only if } S_n \leq t, \quad n = 1, 2, \dots$$

Now define $F^{*n}(t) = \mathbb{P}(S_n \leq t)$, $n = 1, 2, \dots$. Thus, F^{*n} is the distribution of the sum of n independent and identically distributed

random variables (the first n interrenewal times). Then immediately we get

$$M(t) = \sum_{n=1}^{\infty} F^{*n}(t). \quad (2)$$

For this consideration, Equation (2) is an equivalent definition of the renewal function. The convergence of the infinite sum that defines the renewal function is guaranteed [1, Theorem 8.8].

Theorem 1. *The renewal function $M(t)$ is finite for all $t \geq 0$.*

The renewal function plays a central role in renewal theory in the sense that a pure renewal process is completely determined by its renewal function. To see this, first take the Laplace–Stieljes transform (LST) on both sides of Equation (2). Since the renewal function is finite, we get

$$\tilde{M}(s) = \sum_{n=1}^{\infty} \tilde{F}^n(s) = \frac{\tilde{F}(s)}{1 - \tilde{F}(s)}, \quad (3)$$

or

$$\tilde{F}(s) = \frac{\tilde{M}(s)}{1 + \tilde{M}(s)},$$

where $\tilde{M}$ and $\tilde{F}$ are LSTs of M and F respectively. Owing to the uniqueness of the LST, F is completely determined, and so is the renewal process.

Example 1 [Poisson Process]. For a Poisson process with mean arrival rate λ , the interrenewal time distribution is exponential, that is, $F(t) = 1 - e^{-\lambda t}$ and $\tilde{F}(s) = \lambda/(s + \lambda)$. By Equation (3), $\tilde{M}(s) = \lambda/s$. Inverting this we get

$$M(t) = \lambda t, \quad t \geq 0.$$

In other words, a renewal process with a linear renewal function must be a Poisson process.

RENEWAL ARGUMENT AND RENEWAL EQUATION

The renewal argument is one of the most useful tools in renewal theory. The method involves two steps: conditioning on the epoch of the first renewal and then exploiting the regenerative feature of recurrent event. The renewal argument is used to derive an integral equation for certain probabilistic quantities in a renewal process. This section illustrates the renewal argument by deriving the *renewal equation*, which can also be used to compute the renewal function.

Let us compute $M(t)$ by conditioning on the first renewal epoch S_1 , namely,

$$M(t) = \int_0^\infty \mathbb{E}(N(t) | S_1 = x) dF(x).$$

If $x > t$, then the first renewal occurs after t and hence $N(t)$ is 0. If $x \leq t$, then $N(t)$ equals 1 (counting the one that occurs at time x) plus the number of renewals afterwards, up to time t . This is identical in distribution to $N(t - x)$, because we get a replica of the original renewal process after remarking the renewal epoch x as zero. So the integral above equals $\int_0^t \mathbb{E}(1 + N(t - x)) dF(x)$. Therefore,

$$M(t) = F(t) + \int_0^t M(t - x) dF(x). \quad (4)$$

Equation (4) is called a renewal equation. Notice that taking the LST on both sides yields $\tilde{M}(s) = \tilde{F}(s) + \tilde{M}(s)\tilde{F}(s)$, which gives Equation (3).

RENEWAL-TYPE EQUATIONS

This section introduces a class of integral equations that arise from the use of the renewal argument. *Renewal-type equations* are equations of the following form

$$H(t) = D(t) + \int_0^t H(t - u) dF(u),$$

where F is a distribution function of a nonnegative random variable that is almost surely bounded, D is given, and H is the unknown. The renewal equation such as

(4) is a special case of the renewal-type equations with $D = F$. The following theorem [1, Theorem 8.10] gives the conditions for the existence and uniqueness of the solution to a renewal-type equation.

Theorem 2. *Suppose*

$$|D(t)| < \infty \text{ for all } t \geq 0.$$

Then there exists a unique solution to the renewal-type equation

$$H(t) = D(t) + \int_0^t H(t - u) dF(u),$$

such that

$$|H(t)| < \infty \text{ for all } t \geq 0,$$

given by

$$H(t) = D(t) + \int_0^t D(t - u) dM(u),$$

where M is the renewal function as in Equation (2).

This theorem reveals the importance of the renewal function as a factor in the solution of the renewal-type equation. The importance of the renewal-type equation derives largely from a significant result in renewal theory, the *key renewal theorem* (see **Limit Theorems for Renewal Processes**).

In practice, if D has an LST $\tilde{D}$, then the transform version of the renewal-type equation,

$$\tilde{H}(s) = \tilde{D}(s) + \tilde{H}(s)\tilde{F}(s),$$

can be more useful.

In certain applications, one may be interested in an unknown F , where the distribution of interrenewal time, however, is difficult

to compute directly. In such situations, it can be helpful to find a renewal argument that establishes a renewal-type equation involving known H and D functions.

NOTES

The reader is encouraged to continue to article *Limit Theorems for Renewal Processes* on limit theorems, so that the notions of renewal function and renewal equation anchor to the grand picture of renewal theory. A classical and comprehensive reference for this topic is Feller [2, Chapter 11]. Other references include Karlin and Taylor [3], Resnick [4], and Ross [5].

RENEWAL PROCESSES WITH COSTS AND REWARDS

MARIA VLASIOU
Department of Mathematics
and Computer Science,
Eindhoven University of
Technology, Eindhoven,
The Netherlands

BASIC NOTIONS AND RESULTS

Many applications of renewal theory involve rewards or costs (which can be simply seen as a negative reward). For example, consider the classical example of a renewal process: a machine component gets replaced upon a failure or upon having operated for T time units. Then the time the n th component is in service is given by $Y_n = \min\{X_n, T\}$, where X_n is the life of the component. In this example, one might be interested in the rate of the number of replacements in the long run. An extension of this basic setup is as follows. A component that has failed will be replaced at a cost c_f , while a component that is replaced while still being operational (and thus at time T) costs only $c < c_f$. In this case, one might be interested in choosing the optimal time T that minimizes the long-run operational costs. The solution to this problem involves the analysis of *renewal processes with costs and rewards*.

Motivated by the above, let $\{N(t), t \geq 0\}$ be a renewal process with interarrival times X_n , $n \geq 1$, and denote the time of the n th renewal by $S_n = X_1 + \dots + X_n$. Now suppose that at the time of each renewal a reward is received; we denote by R_n the reward received at the end of the n th cycle. We further assume that (R_n, X_n) is a sequence of i.i.d. random variables, which allows for R_n to depend on X_n . For example, $N(t)$ might count the number of rides a taxi gets up to time t . In this case, X_n is the length of each trip, and one reasonably expects the fare R_n to depend on X_n . As usual, we denote by

(R, X) the generic bivariate random variable that is distributed identically to the sequence of rewards and interarrival times (R_n, X_n) . In the analysis, together with the standard assumption in renewal processes that the interarrival times have a finite expectation $\mathbb{E}[X] = \tau$, we further assume that $\mathbb{E}[|R|] < \infty$. The cumulative reward up to time t is given by $R(t) = \sum_{n=1}^{N(t)} R_n$, where the sum is taken to be equal to zero in the event that $N(t) = 0$. Depending on whether the reward is collected at the beginning or at the end of the renewal period, one might wish to adapt this definition by taking $R(t) = \sum_{n=1}^{N(t)+1} R_n$.

The importance of renewal processes with costs and rewards is evidenced by their application to Markovian processes and models. Most queueing processes in which customers arrive according to a renewal process are regenerative processes (see **Regenerative Processes**) with cycles beginning, e.g., each time an arrival finds the system empty. Moreover, for every regenerative process $Y(t)$ we may define a reward structure as follows: $R_n = \int_{S_{n-1}}^{S_n} Y(t) dt$, where all R_n , $n \geq 1$, are i.i.d., except possibly for R_1 that might follow a different distribution. The basic tools that are used are the computation of the reward per unit of time and the rate of the expected value of the reward. These two results are summarized in the following theorem.

Theorem 1. *Let $N(t)$ be a renewal reward process generated by (R, X) , $n \geq 1$. Assume that $\mathbb{E}[|R|] < \infty$ and let $r = \mathbb{E}[R]$, $\tau = \mathbb{E}[X] < \infty$. Then*

$$\lim_{t \rightarrow \infty} \frac{R(t)}{t} = \frac{r}{\tau}, \text{ with probability 1, and} \quad (1)$$

$$\lim_{t \rightarrow \infty} \frac{\mathbb{E}[R(t)]}{t} = \frac{r}{\tau}. \quad (2)$$

These results do not depend on whether rewards are collected at the beginning of the renewal cycle or at its end, or if they are collected in a more complicated manner (e.g., continuously or in a nonmonotone way

during the cycle), as long as (R_n, X_n) , $n \geq 1$ is a sequence of i.i.d. bivariate random variables and minor regularity conditions hold; see the following section. Moreover, the results remain valid also for delayed renewal reward processes, that is, when the first cycle might follow a different distribution.

Note that Equation (2) does not follow from Equation (1), since almost sure convergence does not imply the convergence of the expected values. Think of the distribution

$$\mathbb{P}[Y_n = x] = \begin{cases} n/(n+1), & x = 0, \\ 1/(n+1), & x = n+1. \end{cases}$$

Since for all n , $\mathbb{E}[Y_n] = 1$, we have $\lim_{n \rightarrow \infty} \mathbb{E}[Y_n] = 1$. Moreover, Y_n goes almost surely to zero, that is, $\mathbb{P}[\lim_{n \rightarrow \infty} Y_n = 0] = 1$, which means that the value of the random variable and its expectation differ in the limit.

Proof. To prove Equation (1), write

$$\frac{R(t)}{t} = \frac{\sum_{n=1}^{N(t)} R_n}{N(t)} \frac{N(t)}{t}.$$

By the strong law of large numbers we have that

$$\lim_{t \rightarrow \infty} \frac{\sum_{n=1}^{N(t)} R_n}{N(t)} = \mathbb{E}[R] = r,$$

since $N(t)$ goes to infinity almost surely, and by the strong law for renewal processes we know that

$$\lim_{t \rightarrow \infty} \frac{N(t)}{t} = \frac{1}{\mathbb{E}[X]} = \frac{1}{\tau}.$$

The proof of Equation (2) is a bit more involved. The classical proof applies Wald's equation [1] and requires the proof that $\lim_{t \rightarrow \infty} \frac{\mathbb{E}[R_{N(t)+1}]}{t} = 0$, by constructing a renewal-type equation (see **Renewal Function and Renewal-Type Equations**). Here, we present an alternative proof that follows the same steps of the classical proof for the Elementary Renewal Theorem (See e.g.[2]) but seems to be new in the setting of renewal reward processes.

We first construct a lower bound. From Fatou's lemma, we have that

$$\begin{aligned} \liminf_{t \rightarrow \infty} \frac{\mathbb{E}[R(t)]}{t} &\geq \mathbb{E} \left[\liminf_{t \rightarrow \infty} \frac{R(t)}{t} \right] \\ &= \mathbb{E} \left[\lim_{t \rightarrow \infty} \frac{R(t)}{t} \right] = \frac{r}{\tau} \end{aligned} \quad (3)$$

from Equation (1).

For the upper bound, we use truncation. Take $M < \infty$ and set $R_n^M = \max\{R_n, -M\}$. Note that

$$R(t) = \sum_{n=1}^{N(t)} R_n \leq \sum_{n=1}^{N(t)} R_n^M \stackrel{\text{def}}{=} R^M(t).$$

We then have that

$$\begin{aligned} \frac{\mathbb{E}[R(t)]}{t} &\leq \frac{\mathbb{E}[R^M(t)]}{t} \\ &= \frac{\mathbb{E} \left[\sum_{n=1}^{N(t)+1} R_n^M - R_{N(t)+1}^M \right]}{t} \\ &= \frac{\mathbb{E}[N(t)+1] \mathbb{E}[R_1^M]}{t} - \frac{\mathbb{E}[R_{N(t)+1}^M]}{t} \\ &\leq \frac{\mathbb{E}[N(t)+1]}{t} \mathbb{E}[R_1^M] + \frac{M}{t}. \end{aligned}$$

The last equality follows from Wald's equation since $N(t)+1$ is a stopping time, and for the last inequality we simply observe that we can bound $-\mathbb{E}[R_n^M]$ from above with M (by construction). Thus,

$$\begin{aligned} \limsup_{t \rightarrow \infty} \frac{\mathbb{E}[R(t)]}{t} &\leq \limsup_{t \rightarrow \infty} \left(\frac{\mathbb{E}[N(t)+1]}{t} \mathbb{E}[R_1^M] + \frac{M}{t} \right) \\ &= \frac{\mathbb{E}[R_1^M]}{\tau} \end{aligned}$$

by the Elementary Renewal Theorem. Since we can choose any $M < \infty$ in our construction, by monotone convergence we have that $\mathbb{E}[R_1^M] \rightarrow \mathbb{E}[R_1] = r$ as $M \rightarrow \infty$.

The advantage of this proof is that it avoids the computation of $\lim_{t \rightarrow \infty} \frac{\mathbb{E}[R_{N(t)+1}]}{t}$, and that it is, in essentials, identical to the classical proof for the corresponding theorem in renewal processes without rewards.

PARTIAL REWARDS

In some applications, rewards might not be given at the beginning or at the end of a cycle, but might be earned in a continuous (maybe nonmonotone) fashion during a cycle. The simplest case is when the reward during a cycle is given at a constant rate during the cycle, or only a portion thereof. The portion of the reward up to time t associated with a cycle starting at $X_{N(t)}$ is called a *partial reward*. Recall that we have assumed that $E[X] < \infty$ and $E[|R|] < \infty$. Under further assumptions, Theorem 1 still holds. In the case of partial rewards, we need to assume some form of good behavior as nothing so far prevents the rewards from escaping to plus or minus infinity while still having the average reward per cycle being finite. As an example, to avoid such erratic behavior, consider the restrictive assumption that the absolute value of rewards is uniformly bounded by some number; then Theorem 1 holds. This is also the case when rewards are nonnegative or if they accumulate in a monotone manner over any interval. Wolff [3] assumes that the partial reward during a cycle is the difference of two different monotone nonnegative processes, which could be interpreted as income and costs over the renewal cycle.

It seems to be a standard misconception that only having $E[|R|] < \infty$ is sufficient for Theorem 1 to hold also for partial rewards. In lack of necessary and sufficient conditions in the literature for this result, or at least of a counterexample where $E[|R|] < \infty$, but where Theorem 1 does not hold for partial rewards, we present here a counterexample that illustrates the needs for additional assumptions. In this case, the average reward over a cycle is finite (and we construct it to be equal to zero), but the average reward for every finite t is not defined, and thus also not its limit over t ; see Equation (2).

Take a renewal reward process that is defined as follows: $X_i = 1$ and $R_i = 0$ for all i . During a cycle, rewards build up and are depleted in the following manner. For cycle j , choose a Cauchy random variable C_j and take the auxiliary function $f(x) = x$ for $x \in [0, 1/2]$ and $f(x) = 1 - x$ for $x \in [1/2, 1]$. Define the reward for any time t during cycle j as

$C(t) = C_j \cdot f(t - [t])$. Then we see that the cumulative reward up to time t , for all $t > 0$, is given by $R(t) = C(t)$. Thus, since a Cauchy random variable does not have a well-defined first moment, we see that the average cumulative reward in this example cannot be defined, and thus Theorem 1 cannot be extended for this case, despite the fact that at the end of a cycle (and thus at all integer times) the cumulative reward is equal to zero.

In the following, we show two examples where partial rewards are assumed.

EXAMPLES

We proceed with a few applications of renewal processes with costs and rewards that exhibit the usefulness of these processes. The first two show how (cyclic) renewal processes can be seen as a special case of renewal processes with costs and rewards, while the last two make use of rewards earned continuously over time. Naturally, an abundance of examples of renewal (reward) processes might be found in Markov processes and chains.

Example 1 [Standard renewal processes]. Observe that the standard renewal process is simply a special case of a renewal reward process, where we assume that the reward at each cycle is equal to 1. In this case, we see, for example, that Equation (2) is simply the Elementary Renewal Theorem.

Example 2 [Alternating renewal processes]. For an alternating renewal process (see *Alternating Renewal Processes*), that is, a renewal process that can be in one of two phases (say ON and OFF), suppose that we earn at the end of a cycle an amount equal to the time the system was ON during that cycle. Alternatively, one may assume that we earn at rate one per unit of time when the system is ON, but one need not consider continuous rewards at this point. Then, the total reward earned in the interval $[0, t]$ is equal to the total ON time in that interval, and thus

by Equation (1) we have, as $t \rightarrow \infty$,

$$\frac{\text{ON time in } [0, t]}{t} \rightarrow \frac{\mathbb{E}[Y_{\text{ON}}]}{\mathbb{E}[Y_{\text{ON}}] + \mathbb{E}[Y_{\text{OFF}}]},$$

where Y_{ON} is a generic ON time in a cycle and equivalently for the OFF times. Thus, for nonlattice distributions, the limiting probability of the system being ON is equal to the long-run proportion of time it is ON. Naturally, these results extend to general cyclic renewal processes, that is, a process with more than two phases [4].

Example 3 [Average time of age and excess]. Let $A(t)$ denote the age at time t of a renewal process generated by $X_n \sim X$, and suppose that we are interested in computing the average value of the age. With a slight abuse of terminology, define this to be equal to

$$\lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t A(s) ds.$$

Suppose now that we are obtaining a reward continuously at a rate equal to the age of the renewal process at that time. Thus, $\int_0^t A(s) ds$ represents the total earnings by time t . Moreover, since the age of a renewal process at time s since the last renewal is simply equal to s , we have that the reward during a renewal cycle of length X is equal to $\int_0^X s ds = X^2/2$.

Then by Equation (1) we have that with probability 1,

$$\lim_{t \rightarrow \infty} \frac{\int_0^t A(s) ds}{t} = \frac{\mathbb{E}[X^2/2]}{\mathbb{E}[X]}.$$

We can apply the same logic to the residual life at time t , $B(t)$, and we will end up at the same result. Since the renewal epoch covering time t is equal to $X_{N(t)+1} = A(t) + B(t)$, we have that

$$\lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t X_{N(t)+1} ds = \frac{\mathbb{E}[X^2]}{\mathbb{E}[X]} \geq \mathbb{E}[X],$$

where we have equality only when $\text{Var}(X) = 0$. Thus, we retrieve the inspection paradox.

Example 4 [Little's law]. Consider a GI/GI/1 stable queue with the interarrival times X_i generating a nonlattice renewal process. Suppose that we start observing the system upon the arrival of a customer. Denote a generic interarrival time by X and let $\mathbb{E}[X] = 1/\lambda$. Also denote by $n(t)$ the number of customers in the system at time t . Consider the average number of customers in the system in the long run, which we denote by L . Then, with a slight abuse of notation we have that

$$L = \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t n(y) dy.$$

Define a renewal reward process with cycles C starting each time an arrival finds the system empty, and suppose that we earn a reward at time y with a rate $n(y)$. Then from Equation (2) we have that

$$\begin{aligned} L &= \frac{\mathbb{E}[\text{reward during a cycle}]}{\mathbb{E}[\text{cycle time}]} \\ &= \frac{\mathbb{E}\left[\int_0^C n(y) dy\right]}{\mathbb{E}[C]}. \end{aligned} \quad (4)$$

Now let N be the number of customers served during a cycle, and define the long-run average sojourn time of customers as $T = \lim_{n \rightarrow \infty} (T_1 + \dots + T_n)/n$, where T_i is the time customer i spent in the system. Take now a cycle of length C where N customers were served. We can see then that the reward we have received in that cycle, which was defined to be equal to a rate of $n(y)$ at each time y , can also be seen as having each customer pay at rate 1 for each time unit he/she is in the system. In other words, in a cycle with N customers, the reward is equal to $T_1 + \dots + T_N$, that is, the total time all customers in that cycle spent in the system. Then T is the average reward per unit time (observe that since the second definition of the reward depends on the number of customers in a cycle, the duration of the cycle is also defined in terms of customers), and

again by Equation (2) we have

$$\begin{aligned} T &= \frac{\mathbb{E}[\text{reward during a cycle}]}{\mathbb{E}[\text{cycle time}]} \\ &= \frac{\mathbb{E}\left[\sum_1^N T_i\right]}{\mathbb{E}[N]}. \end{aligned} \quad (5)$$

We can now prove Little's law, one of the fundamental relations in queueing theory, which states that $L = \lambda T$. To see this, observe that

$$C = \sum_1^N X_i,$$

and since N is a stopping time for the sequence $\{X_i\}$, we have from Wald's equation

$$\mathbb{E}[C] = \mathbb{E}[N]\mathbb{E}[X] = \mathbb{E}[N]/\lambda.$$

Thus, by Equations (4) and (5), we see that

$$L = \lambda T \frac{\mathbb{E}\left[\int_0^C n(y) dy\right]}{\mathbb{E}\left[\sum_1^N T_i\right]}.$$

However, as we have seen, the fraction is equal to 1, since both the numerator and the denominator describe the reward earned during a cycle. Thus, we retrieve Little's law.

FURTHER READING

Almost all books on stochastic processes and introductory probability have a section on renewal theory. Here we only refer to the ones that have a separate mention of renewal processes with costs and rewards. Cox [5] is one of the few manuscripts exclusively devoted to renewal processes, where renewal processes with costs and rewards are found under the term *cumulative processes*. Another term that has been used to describe these processes is *compound renewal processes*. The general concept of a cumulative process and the asymptotic results related to them are based on Smith [6,7]. Mercer and Smith [8] investigate cumulative processes modulated by a Poisson process, in connection with a study of the wear of conveyor

belting. Brief mentions of renewal reward processes can also be found in Taylor and Karlin [9], as well as in Heyman and Sobel [10] in a contribution by Serfozo. In Moder and Elmaghraby [11], one may find a short treatment of cumulative processes, which also includes asymptotic results not only for the expectation of $R(t)$ as given by Equation (2) but also for its variance. As noted in their text, there are multivariate versions of these results as well. The following books offer a thorough treatment of this topic and a multitude of examples; moreover, they are approachable to a wide audience with only undergraduate knowledge of probability theory [3,12–16].

RENT AND RENT LOSS IN THE ICELANDIC COD FISHERY

RAGNAR ARNASON
Department of Economics,
University of Iceland,
Reykjavik, Iceland

In a complete and smoothly operating market system, the net economic benefits of any production activity are measured by its profits [1,2]. In a natural resource-based industry such as fisheries, a part of the profits stem from the natural productivity of the underlying resource. This part may be referred to as natural resource rent or, in the case of the fishery, fisheries rent [3,4].

There is an important difference between fisheries rent and fisheries profit. Fisheries rent constitute that part of variable profits (profits without subtracting fixed costs), which is shared by all fishers. In this sense, the fisheries rents may be seen as a contribution of nature rather than individual ability. Above and beyond the rents, however, the more efficient fishers receive additional variable profits, sometimes referred to as intramarginal profits [5].

A simple example serves to illustrate these concepts. Imagine a fishery of three fishers, each of whom catches one unit of fish. Let the variable profits of the first be US\$10, those of the second US\$9, and those of the third US\$8. Then total profits in this fishery are US\$27 ($10 + 9 + 8$). The rents, however, are US\$24 ($8 \cdot 3$). The intramarginal profits are US\$3 ($2 + 1$).

In well-developed fisheries, intramarginal profits are usually quite small, so profits and rents are similar. The reason is that the knowledge, capital, and techniques generating superior efficiency tend, due to the forces of competition and market trade, to be quickly assimilated by all fishers. Therefore, in spite of technical progress, efficiency tends to be quite uniform across the fleet.

At each point of time, natural resource rents are bounded from above by the

productivity of the resource, the production technology, and input–output prices. These constraints define the maximum rents technically achievable. Obviously, the difference between the maximum rents attainable and the rents actually realized, the so-called rent loss, provides a measure of the economic efficiency of the resource use activity [4].

Ocean fisheries, since they are based on free-ranging ocean fish stocks, are extremely susceptible to the common property problem, that is, economic waste stemming from lack of private property rights in resources [6]. In the fishery, this problem leads to devastated fish stocks and a complete dissipation of all net economic benefits attainable from the fish resource [7]. As a result, the equilibrium state of common property fisheries is characterized by no profits and absence of any economic rents. This is confirmed by empirical observations. Most ocean fisheries in the world do not seem to be generating much net economic benefit or rent [4].

This article obtains a measure of the rent loss in the Icelandic cod fishery by estimating the actual resource rent generated and comparing it to the maximum attainable one. The fisheries rent (hereafter often referred simply to as *rent*) are calculated on the theoretical basis set out in Refs 4 and 5. The cod fishery is modeled in a simple, aggregate way. This is to keep the amount of data and modeling work within reasonable bounds. The construction of a more complete disaggregated model (with respect to substocks, cohorts, vessel classes, and fishing gear) of the Icelandic cod fishery is a major undertaking. Previous research employing both the disaggregate and aggregate approaches [8,9] indicates that the inaccuracies of employing a simple aggregative model for the Icelandic cod fishery rather than a more complete, disaggregated one are insignificant.

The Icelandic cod fishery is a particularly interesting case for a study of this nature. The reason is that this fishery was subjected to individual transferable quotas (ITQs) in stages beginning in 1984 [10]. In 1991, the

coverage of the ITQ system in the Icelandic cod fishery was substantially strengthened and expanded to cover all fishing vessels above 6 GRT (gross registered tons). In 2006, the system was further expanded to cover all commercial fishing vessels. Thus, from 1990 onwards, the Icelandic cod fishery has been managed for the most part on the basis of ITQs.

ITQs represent a certain fisheries management system under which the total allowable catch (TAC) each year is subdivided and allocated to fishers as their individual catch rights (quotas). Subsequently, the fishers may harvest according to these rights or transfer them to others. It is theoretically well-established [11,12] that ITQs lead to efficient fishing operations. First, the individual catch right greatly reduces the common property problem in the fishery. Second, the tradability of the rights allows the less efficient part of the fleet to leave the fishery with a monetary compensation and the TAC to be taken by fewer, more efficient vessels. Third, provided the TACs are set optimally over time so that the fish stocks can revert to their optimal levels—which for biological and ecosystem reasons may take a long time—the fishery will gradually become fully efficient. Obviously, this system promotes an overall gain in economic efficiency of the fishery and the generation of fisheries rent [11,12]. Thus, it is interesting to see to what extent the Icelandic cod fishery actually exhibits these theoretical gains.

In addition to its empirical relevance, this article provides an example of how the method of operations research can be used to derive useful results about a subject of considerable social importance. In this case, knowledge from economics and biology are combined with mathematical techniques to construct a reasonably tractable and theoretically consistent model of a fisheries situation. Numerical techniques are subsequently used to derive estimates of the fishery rent loss. Finally, statistical techniques are employed to assess the uncertainty about the true values and obtain estimates of confidence intervals. Needless to say, the methods outlined in this article can be used to perform similar calculations for other fisheries.

THE ICELANDIC COD FISHERY: BACKGROUND

The Icelandic cod fishery constitutes a sizable segment of the global ocean fishery. Annual catches have traditionally been in excess of 300 thousand metric tons (mt) annually. The unit value of landings is high (prices in 2007 were around US\$3 per kg.). Thus, the landed value of the fishery is potentially almost US\$1 billion. This may be compared to the estimated value of global marine capture fisheries landings of some US\$80 billion [13]. In the past, however, this fishery has been greatly overexploited. As a result, current stocks are quite depressed: estimates suggest that the fishable stock in 2007 was only about 30% of the virgin stock [14].

Cod fishing is pursued throughout the year, with a peak during the spawning season when large fish become highly catchable. It is conducted both, in inshore and off-shore waters by several types of vessels ranging in size from about 5 to 3000 GRT and employing different types of fishing gear. In terms of landed quantity, however, the most important part of the fleet are deep-sea bottom trawlers, typically 500–1500 GRT, many of which are freezer/factory trawlers.

The cod fishery is by far the most valuable component of the Icelandic demersal fisheries. These fisheries involve some 20 species of significance with cod haddock, saithe, redfish, and Greenland halibut (turbot) being the most important. In any given fishing trip, one of these species tends to be targeted. However, it is not common to haul in a clean, one-species harvest. In some fishing trips, especially the longer ones, a mix of two or more species is targeted.

As already mentioned, most vessels pursuing cod and other demersal fisheries were subjected to a form of ITQs in 1984. The ITQ system was substantially strengthened and expanded in 1991 although the smallest vessels (under 6 GRT) were still largely exempted from the ITQ restrictions. These small vessels were brought into the ITQ system in 2004.

Under the ITQ system, especially from 1991 onwards, various steps have been taken to restore the cod stock. Most important of

Figure 1. The cod fishery: fishable biomass and landings (1000 mt).

Figure 2. The haddock fishery: fishable biomass and landings (1000 mt).

these measures have been severe cut-backs in TACs. Other important measures have been extensive time and area closures. As can be gauged from Fig. 1, these measures have halted the decline in the stock, but have not managed to significantly increase it. Interestingly, similar measures for other demersal stocks, most notably the haddock stock, have produced much better results (Fig. 2).

Under the ITQ system, the size of the demersal fishing fleet as well as the demersal fishing effort (including the one on cod) has substantially contracted [10]. This as well as several other measures undertaken by the fishing firms, has greatly increased the economic performance of the fishery. Thus, productivity in the fishing industry has increased at a rapid rate. Similarly, the

profitability of the fishing firms has greatly improved. These developments have been reflected in a huge increase in the market value of the ITQs. These and further data regarding the economic and biological impact of the ITQs are recounted in Refs 10 and 15.

THE COD FISHERIES MODEL

To describe the cod fishery, the following basic fisheries model is adopted:

$$\dot{x} = G(x) - y \text{ (biomass growth function)} \quad (1)$$

$$y = Y(e, x) \quad \text{(harvesting function)} \quad (2)$$

$$\pi = p \cdot Y(e, x) - C(e) \text{ (profit function)} \quad (3)$$

$$p = P(y) \text{ (landings demand function).} \quad (4)$$

The five variables of this model, that is x, y, π, p , and e represent biomass, harvest, profits, landings price, and fishing effort, respectively. The first four are endogenous—determined within the model. The fifth, fishing effort, is exogenous in the sense of being a control variable for the fisheries operators. All variables depend on time, that is, they can change over time. The derivative, $\dot{x} \equiv \partial x / \partial t$ measures the change in biomass at a point of time. Note that parameters taken to be constants, such as various prices and technological coefficients, are not explicitly mentioned in the above presentation of the model.

In implementing the model, the following functional specifications, suggested by econometric investigations of the data [9,16], are employed.

$$x_{t+1} - x_t = G(x_t) = \alpha \cdot x_t - \beta \cdot x_t^2,$$

$$Y(e_t, x_t) = q \cdot e_t^a \cdot x_t^b,$$

$$C(e_t) = c \cdot e_t + fk,$$

$$P(y_t) = d \cdot y_t^f,$$

where $\alpha, \beta, q, a, b, c, fk, d$, and f are constants and t refers to time. Note that time is now measured in discrete years in accordance with the available data. The constant α is the intrinsic growth rate of the biomass, the ratio α/β , is the carrying capacity of the biomass, fk represents fixed costs, q catchability, and f is the elasticity of landings price with respect to the volume of landings.

Given these functional specifications, the complete model can be written in a condensed form as

$$x_{t+1} - x_t = \alpha \cdot x_t - \beta \cdot x_t^2 - y_t$$

(biomass growth function) (5)

$$\pi_t = p_t \cdot y_t - k \cdot \frac{y_t^\delta}{x_t^\varepsilon} - fk$$

(profit function) (6)

$$p_t = d \cdot y_t^f \quad (\text{price function}) \quad (7)$$

In this formulation fishing effort, e , has been substituted out. The endogenous variables

Table 1. Estimated Coefficients

Coefficients	Estimates	t -statistics
α	0.669853	8.6
β	$3.353 \cdot 10^{-4}$	-2.9
k	57604.95	6.5
δ	1.1	NA (nonlinear estimate)
ε	1.0	NA (restricted)
fk	10 billion	NA (from cost accounts)
d	220.0	14.8
f	0	NA (restricted)

Note: Economic values are in ISK. Exchange rate: 61 ISK per US\$.

are now x, π , and p . The exogenous (or control) variable is y . It is easy to check that the new constants k, δ , and ε are the following transformation of the original constants: $k = \frac{c}{q^{1/a}}, \delta = 1/a$ and $\varepsilon = b/a$.

Econometric and other estimation of the constants in the cod model defined by Equations (5), (6) and (7) led to the following results (Table 1) [16,17].

For the biomass function it is easy to verify that the maximum sustainable yield MSY and the stock carrying capacity XMAX, say, are given by the expressions:

$$\text{MSY} = \frac{\alpha^2}{4 \cdot \beta},$$

$$\text{XMAX} = \frac{\alpha}{\beta}.$$

It then follows from the estimates in Table 1 that the estimated MSY = 335 and the estimated XMAX = 1998 thousand mt.

Figure 3 provides a summary description of this fishery. The figure is drawn in the space of (fishable) biomass and landings (harvest) and applies at each point of time and, therefore, also in equilibrium. The parabolic graph represents the biomass growth function. As can be seen, it covers biomass from zero to the carrying capacity of almost 2 million mt and has an MSY of about 335 thousand mt. If, for any biomass level, landings lie on this curve, a biological equilibrium prevails. The other curves in this diagram are variable iso-profit curves, that is, loci of biomass and harvests which represent constant variable profits (measured in cod volume units). These functions are obtained by selecting a fixed level of

Figure 3. The estimated fisheries model (biomass growth and iso-profits in (biomass, harvest)-space).

Table 2. Rents and Rent Drain: Main Results

	Current (2005)	Maximum	Difference
Biomass (1000 mt)	715	1241	+526
Harvest (1000 mt)	215	315	+100
Effort (index)	1.0	0.86	-0.14
Total profits (million US\$)	126	546	+420
Variable profits (million US\$)	290	710	+420
Rents (million US\$)	241	667	+426

Note: Financial amounts in million US\$ per year.

profits in Equation (6) and tracing out the corresponding biomass, harvest coordinates. Any point where these iso-profit curves intersect the biomass growth curve represents a sustainable fishery with the corresponding variable profits. Thus, the traditional, zero-profit bioeconomic equilibrium is found where the zero-isoprofit curve intersects the biomass equilibrium curve. This happens, as indicated in the diagram, roughly where biomass is less than a quarter of the virgin stock equilibrium. The highest sustainable profits are obtained where an iso-profit curve is a tangent to the biomass growth function. As the diagram suggests, this occurs at a biomass of some 1300 thousand mt and harvest of over 300 thousand mt. At this point, annual variable profits from the fishery (approximately rents) amount to approximately 200 thousand mt of cod.

ESTIMATE OF RENT AND RENT LOSS

According to Refs 4 and 5, rents are defined as

$$\text{Rents}_t = \left(\frac{d\pi_t}{dy_t} \right) \cdot y_t,$$

where π_t represents profits and y_t harvest. For the profit function specified in the section titled “The Cod Fisheries Model,” this equation is

$$\text{Rents}_t = p_t \cdot y_t - k \cdot \delta \cdot \frac{y_t^\delta}{x_t^\varepsilon}. \quad (8)$$

Comparison with the profit function (6) shows that in this case, rents are unambiguously less than variable profits. This is because the profit function is strictly concave in harvest ($\delta > 1$). Note that because of the fixed costs, the rents may be greater or less than total

profits, depending on the level of harvest and biomass.

Given (8) and the fisheries model specified above, it is now an easy matter to estimate actual rent and rent loss. The latter, as explained in the introduction, is merely the difference between maximum attainable rent and current rent. In these calculations, the actual rent is calculated relative to conditions in 2005, the last year for which estimates of parameters and cod stock sizes are available. The estimated base year rent is referred to as the *current rent* below. The maximum rent is the maximum sustainable rent (Table 2).

So, it appears that in spite of its biologically depressed state, the Icelandic cod fishery is currently generating substantial economic rent as well as profit. However, compared to the maximum attainable rent, the fishery suffers from rent loss of some US\$426 million per year. In terms of current rent and the size of the fishery, this rent loss is very substantial. It should be noted, however, that to realize the maximum potential rent from this fishery, extensive rebuilding of the cod stock is required—a goal that has not been accomplished in spite of quite dramatic reduction in TAC levels since the early 1990s, and to a lesser extent, reduction in long-term fishing capital and effort. The former leads to substantial increase in sustainable catches that will be responsible for most of the economic gain.

The finding that the Icelandic cod fishery is apparently generating significant economic rent constitutes empirical evidence in support of the economically beneficial impact of the ITQ fisheries management system. That this rent appears to constitute less than 40% of the maximum attainable ones draws attention to the practical limitations of long overdue fisheries management. Before the introduction of the ITQ system, the Icelandic cod stock was subject to heavy overexploitation for decades. This will inevitably have altered ecosystem conditions, possibly to the point of transition to a different equilibrium attraction domain, and it may have adversely impact the genetic composition of the stock. As a result, it has proven much more difficult to restore the stock to economically optimal levels than predicted by the biological models.

UNCERTAINTY AND CONFIDENCE INTERVALS

The above estimates are subject to uncertainty and this uncertainty has many sources. There is uncertainty about the current state of the fishery, which is needed to estimate current rents. Similarly, there is uncertainty about the values of the parameters of the model used to calculate maximum future rents. Finally, there is uncertainty about the model itself. The first three types of uncertainty may be expressed as uncertainty about the numerical specifications of the current fishery and model parameters and the current state of the fishery. The importance and extent this uncertainty may be assessed by stochastic or Monte Carlo simulations [18].

Sensitivity analysis suggests that the estimated rent loss is most sensitive to the following: (i) initial stock size, (ii) MSY, (iii) carrying capacity of the biomass (i.e., XMAX) and (iv) price of landed catch, p . Hence, it makes sense to explore the uncertainty regarding these empirical estimates by stochastic simulations.

The stochastic simulations employed in this article are quite simplistic. Stochastic distributions for five model variables/coefficients, namely (i) landings price, (ii) initial biomass, (iii) cost coefficient, k , (iv) the estimated MSY, and (v) the estimated carrying capacity of the stock, XMAX, were specified. In all cases, the stochastic specifications took the form

$$z_i = \bar{z}_i \cdot (1 + u_i),$$

where z_i denotes the stochastic value of variable i , $\bar{z}_i$ the value specified in the section titled “The Cod Fisheries Model” above (especially Table 1 and below) and u_i is a normally distributed random variable with zero mean and some variance to be specified. It follows that each stochastic quantity z_i is normally distributed with expected value $\bar{z}_i$ and standard deviation $\bar{z}_i \cdot \sigma_i$ where σ_i is the standard deviation of variable i .

The stochastic specifications employed in the simulations are summarized in Table 3.

Two thousand random draws were drawn from the distributions specified in Table 3. For each set of draws, rent in the base

Table 3. Stochastic Specifications

Variable	Stochastic Version	Distribution of the Random Term	Expected Value	Standard Deviation
Landings price, p	$\bar{p} \cdot (1 + u_p)$	$u_p \sim N(0, 0.03)$	220	11
Initial biomass	$\bar{x} \cdot (1 + u_x)$	$u_x \sim N(0, 0.05)$	715	100
Cost parameter, k	$\bar{k} \cdot (1 + u_k)$	$u_k \sim N(0, 0.1)$	57605	5761
MSY	$\overline{\text{MSY}} \cdot (1 + u_{\text{MSY}})$	$u_{\text{MSY}} \sim N(0, 0.05)$	335	17
XMAX	$\overline{\text{XMAX}} \cdot (1 + u_{\text{XMAX}})$	$u_{\text{XMAX}} \sim N(0, 0.07)$	1998	140

**Figure 4.** Stochastically simulated rent loss: a histogram.**Figure 5.** Rent loss: an estimated distribution function.

year and maximum rent, and the difference between the two were calculated. Each difference represents one possible rent loss. The distribution of all these two thousand outcomes represents an estimate of the probability distribution of the rent loss. The corresponding histogram of rent loss is illustrated in Fig. 4.

As may be inferred from Fig. 4, the distribution of rent loss is skewed slightly to the right (a longer tail to the right). The coefficient of skewness was 0.314 (compared to zero for a normal distribution). Thus, the distribution is not quite normal. In accordance with this, the estimated mean rent loss was US\$428 million and the estimated median loss was US\$422 million. Compare this to the non-stochastic estimate of random loss derived in the section titled “Estimate of Rent and Rent Loss” (especially Table 2) of US\$426 million.

An estimated distribution function for the outcomes is drawn in Fig. 5. On the basis of this distribution function, confidence intervals for the rent loss are easy to calculate. A 95% confidence interval for the rent loss is US\$233 to 655 million. A 90% confidence

interval for the rent loss is US\$257 to 610 million.

SUMMARY AND CONCLUSION

According to the above, current (year 2005) total rent in the Icelandic cod fishery amounts to about US\$240 million annually. Maximum attainable annual rent, however, is estimated to be US\$667 million. Thus, the difference between current rent and maximum attainable rent, that is the rent loss, is estimated to be US\$426 million.

The main reason for the rent loss or submaximal generation of fisheries rent in the Icelandic cod fishery is the depressed state of the cod stock. Over the past several years, determined attempts have been made to restore this stock to its long-run optimal levels by imposing very restrictive TACs as compared to historical standards. Recent TACs for cod have been only about 40% of the estimated MSY and an even smaller fraction of the average harvest levels between 1970 and 1990. There are now signs that these

attempts may be bearing fruit and that the stock is slowly recovering. Nevertheless, it will probably take an additional 5 to 10 years to restore the stock to the level where it can generate the full economic rent of US\$667 million on a sustainable basis.

These numerical results concerning rents and rents loss are based on a fairly simplistic representation of the fishery, estimates of empirical quantities which cannot be accurate and several numerical approximations. Consequently the results cannot be very precise. Sensitivity analysis suggests that the calculated rents loss are most sensitive to the empirical assumptions about the initial stock size, the MSY, the carrying capacity of the biomass and the price of landed catch. Stochastic simulations over these and other empirical specifications suggest a 95% confidence interval for the rent loss of US\$233–655 million.

In spite of this comparatively high degree of uncertainty about the true numbers, the main message seems reasonably robust. The Icelandic cod fishery, in spite of being biologically quite depressed, is currently generating substantial economic rent. The rent, however, is less than half, perhaps as low as one-third of the maximum attainable one in sustainable equilibrium. To reach that point, the cod biomass must be increased greatly (almost by three-fourths) and fishing effort reduced by about one-sixth. Needless to say, this kind of change cannot be effected quickly—most likely, it will take several years even if all fishing for cod was immediately halted. It follows that in terms of present value, the potential rent gain is substantially less than that suggested above.

REPAIRABLE SYSTEMS: RENEWAL AND NONRENEWAL

STEVEN E. RIGDON

Department of Mathematics and Statistics,
Southern Illinois University, Edwardsville,
Illinois

OVERVIEW

When a system can be repaired upon failure, thereby bringing it to an operating condition, the system is said to be repairable. This repair could, but usually does not, mean complete replacement of the system. In contrast, a nonrepairable system is one that is usually not repaired upon failure. Items that were once considered repairable, such as a computer monitor or a handheld calculator, are now often discarded after failure because the replacement cost is lower than the repair cost. Automobiles, airplanes, and copy machines are examples of repairable systems, because the replacement cost is normally much higher than the repair cost.

For a repairable system, a model must account for the occurrence of events in time. We can describe such a model by using the actual failure times

$$0 < T_1 < T_2 < \cdots < T_n < \cdots,$$

measured from the initial start-up of the system. Time measured from system start-up is called *global time*. Alternatively, a model may describe the times between events or failures,

$$X_1, X_2, \dots, X_n, \dots,$$

Interevent times are measured in *local time*. Of course, these variables are related by

$$\begin{array}{ll} T_1 = X_1, & X_1 = T_1, \\ T_2 = X_1 + X_2, & X_2 = T_2 - T_1, \\ T_3 = X_1 + X_2 + X_3, & X_3 = T_3 - T_2, \\ \vdots & \vdots \end{array}$$

We say that a repairable system is *deteriorating* if the times between failure tend to get shorter, and we say that it is *improving* if the times between failures tend to get longer. Ebrahimi [1] gives a more precise and thorough description of deterioration and improvement.

EXAMPLES

In this section, we give a number of examples of data from repairable systems. Then in the section titled “Examples Revisited,” we consider the analysis of these data.

Example 1. Consider the failure times for the USS Halfbeak main propulsion engine [2]. Some of the failure times, measured in global time, are shown in Table 1. The plot of cumulative operating time against cumulative failure number is shown in Fig. 1. For this system, the failures seem to be getting closer together, indicating deterioration. Table 2 shows the number of failures in each 2000-h interval, indicating clearly that the rate of occurrence of failures (ROCOF) increases with the age of the system.

Table 1. Failure Times of USS Halfbeak

Failure number	Failure time	Time between failure
1	1,382	1,382

Example 2. Table 3, from Ref. 3, shows the failure times of a photocopy machine. Here, time is measured not in hours or days, but in the number of copies made. Similarly, the age of an automobile is often measured in miles, not years. The data seem to show neither improvement nor deterioration.

Example 3. Balaban [4] gave an example of the failures of a mechanical system. The failures during each month are shown in Table 4. This example differs from the previous examples, because the exact failure times are not known. All that is known is that a certain number of failures occurred in each month with a certain number of operating hours. This system seems to indicate improvement, because one-third of all failures occurred in the first two months,

Table 3. Failure Times, Measured in Number of Copies, for Copy Machine

Failure number	Copy count	Failure number	Copy count
1	2,827	10	131,832

time, that is, the time that data collection stopped, is included in Table 6. A system that experiences no failures still contains information about the failure process. For example, system 1 contained no failures in 761 time units of operation, giving us some (but not much) information about the rate of occurrence of failures for that system.

NONREPAIRABLE SYSTEMS

Many concepts regarding repairable systems have direct analogs to concepts for nonrepairable systems, so we present a

brief review. Typically, the lifetime for a nonrepairable system is a random variable T . Let the PDF, CDF, and survivor function for T be denoted by $f(t)$, $F(t)$, and $S(t)$, respectively. The hazard function is the limit of a conditional probability

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{P(t \leq T < t + \Delta t | T \geq t)}{\Delta t}.$$

An increasing hazard indicates that the probability of an imminent failure increases with the age of the system, an indication of the system wearing out. It can be shown [3] that

$$h(t) = \frac{f(t)}{S(t)}.$$

In some books, this is taken as the definition, although the limit definition is often preferred because it gives insight into what the hazard measures. Leemis [7] gives a table showing the relationships between the PDF, CDF, survivor function, and hazard function.

Three commonly used lifetime distributions are the exponential, the Weibull, and the gamma. The exponential distribution with mean θ , denoted $\text{EXP}(\theta)$, has PDF

$$f(t) = \frac{1}{\theta} e^{-t/\theta}, \quad t > 0.$$

The hazard function for the exponential distribution is the constant $h(t) = \frac{1}{\theta}$. In addition, the exponential distribution has the memoryless property,

$$P(T > t + x | T > t) = P(T > x);$$

that is, given survival to time t , the probability of survival of an additional x time units is equal to the probability that a new unit survives x units. Thus, age does not affect the probability of survival.

The Weibull distribution, denoted $\text{WEI}(\beta, \theta)$ has PDF

$$f(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta}\right)^{\beta-1} \exp\left(-\left(\frac{t}{\theta}\right)^\beta\right), \quad t > 0.$$

The mean for the Weibull distribution is $\mu = \theta \Gamma(1 + 1/\beta)$ and the hazard function is

$$h(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta}\right)^{\beta-1}.$$

The Weibull distribution, unlike the exponential, can model systems that have an increasing or a decreasing hazard function, but it cannot model lifetimes that have a hazard function that is sometimes increasing and sometimes decreasing.

The gamma distribution, denoted $\text{GAM}(\kappa, \theta)$ has PDF

$$f(t) = \frac{t^{\kappa-1}}{\theta^\kappa \Gamma(\kappa)} e^{-t/\theta}, \quad t > 0.$$

The mean of this distribution is $\mu = \kappa\theta$. The hazard function is

$$h(t) = \frac{\frac{t^{\kappa-1}}{\theta^\kappa \Gamma(\kappa)} e^{-t/\theta}}{\int_t^\infty \frac{u^{\kappa-1}}{\theta^\kappa \Gamma(\kappa)} e^{-u/\theta} du} = \frac{t^{\kappa-1} e^{-t/\theta}}{\int_t^\infty u^{\kappa-1} e^{-u/\theta} du},$$

which converges to the value $1/\theta$ as $t \rightarrow \infty$.

For systems that have a high hazard when very young, followed by a fairly constant one, followed by a rapidly increasing hazard, a bathtub hazard is appropriate. Figure 2 illustrates this.

REPAIRABLE SYSTEMS: RENEWAL

When a system is repaired to a like-new condition, or if repair means complete system replacement, then the renewal process is used as a process model. The renewal process assumes that the times between failures $X_1, X_2, \dots$ are independent and identically distributed.

For any counting process, that is, the process that describes the occurrence of events in time, the complete intensity function is defined to be

$$\lambda(t | \mathcal{H}_t) = \lim_{\Delta t \rightarrow 0} \frac{P(\text{a failure occurs in } [t, t + \Delta t] | \mathcal{H}_t)}{\Delta t},$$

where $\mathcal{H}_t$ is the entire history of the process up to time t . If the distribution of the times between failures has an increasing hazard that begins with $h(0) = 0$, as for example the Weibull distribution does when $\beta > 1$, then

Figure 2. For a bathtub-shaped hazard function, there is a large hazard for very new components, followed by a period of roughly constant hazard and finally, wear out.

Figure 3. Complete intensity function for a renewal process with increasing hazard function, conditioned on failures at times 8, 11, 24, and 35.

the complete intensity function will increase from zero until a failure occurs; then it will reset to zero and increase until the next failure, and continue this process as long as the system operates. This is illustrated in Fig. 3. Care must be taken, however, to interpret this plot; it is conditioned on the failures at times 8, 11, 24, and 35.

Let

$$\Lambda(t) = E[\text{number of failures in } [0, t]].$$

The derivative $\mu(t) = \Lambda'(t)$ is called the *ROCOF*, or sometimes the *renewal density*. It turns out that the ROCOF is equal to limit of unconditional probabilities

$$\mu(t) = \lim_{\Delta t \rightarrow 0} \frac{P(\text{a failure occurs in } [t, t + \Delta t])}{\Delta t},$$

provided that simultaneous failures have probability zero [2]. It is not difficult to show that the ROCOF is equal to

$$\mu(t) = \sum_{k=1}^{\infty} f^{(k)}(t),$$

where $f^{(k)}(t)$ is equal to the PDF of the time of the k th failure, measured in global time, that is, the time since the initial start-up of the system [3].

Figure 4 shows the PDFs for the failure times (measured in global time) for a gamma renewal process, where the times between failure are IID $\text{GAM}(20, \frac{1}{10})$. The mean of this distribution is $20 \times \frac{1}{10} = 2$ and the variability is fairly low. The ROCOF, shown in Fig. 5, oscillates, but converges to 0.5, which is the reciprocal of the mean. This is to be

Figure 4. PDFs for time-to-failure for $k = 1, 2, 3, 4, 5, 6$, and 7 . These times between failure will tend to be more evenly spaced.

Figure 5. ROCOF for renewal process for which the PDFs for failure times are in Fig 4.

expected; if failures occur on average every 2 h, then in the long run, failures will occur at the rate of one per 2 h, or 0.5 failures per hour.

The results about the asymptotic behavior of the ROCOF are guaranteed by the next theorem.

Theorem 1. *For a renewal process with IID times between failure $X_1, X_2, \dots$, and $\eta = E(X_i)$,*

1. $\lim_{t \rightarrow \infty} \frac{\Lambda(t)}{t} = \frac{1}{\eta},$
2. $\lim_{t \rightarrow \infty} \mu(t) = \frac{1}{\eta}.$

See Ref. 3 for a proof.

In a renewal process situation, we typically know the distribution of the times between failure, that is, we know the PDF $f(x)$ and the CDF $F(x)$. The functions $\Lambda(t)$ and $\mu(t)$ are usually more difficult to obtain. There are, however, integral equations that express the relationships among these functions. Rigdon and Basu [3, pp. 72–73] show that $\Lambda(t)$ and $\mu(t)$ satisfy the following integral equations:

$$\Lambda(t) = F(t) + \int_0^t \Lambda(t-y)f(y)dy$$

and

$$\mu(t) = f(t) + \int_0^t \mu(t-y)f(y)dy.$$

If the repair time is taken into account, we can ask for the probability that the system is available at time t . The system availability, as a function of time t , is

$$A(t) = S(t) + \int_0^t S(t-y) \mu(y) dy.$$

This can be explained intuitively by saying that the system is available at time t if and only if one of the two conditions hold:

1. The system has operated with no failures up to time t . This occurs with probability $S(t)$.
2. The system has operated with no failures since the last repair. Conditioning on the time of the last repair and integrating gives us a probability of

$$\int_0^t S(t-y) \mu(y) dy.$$

The availability is thus, the sum of these two probabilities.

The average availability over the interval $[0, T]$ is defined to be

$$A_{\text{avg}}(t) = \frac{1}{T} \int_0^T A(t) dt.$$

The steady-state availability is the limit of the availability function as $t \rightarrow \infty$

$$A_{\text{ss}} = \lim_{t \rightarrow \infty} A(t) = \frac{E(X)}{E(X) + E(R)},$$

where X is the time-to-failure and R is the repair time. The steady-state availability can then be written as

$$A_{\text{ss}} = \frac{MTBF}{MTBF + MTTR}$$

where MTBF is the mean time-between-failures and MTTR is the mean time-to-repair. This steady-state formula makes intuitive sense; if a system fails on average every 9 h and it takes 1 h to repair it on average, then we would expect it to be working 9 times out of 10, for an availability of 0.9.

REPAIRABLE SYSTEMS: POISSON PROCESSES

The simplest model for repairable systems is the homogeneous Poisson process (HPP). Suppose we have a counting process where $N(t)$ is the (random) number of events in the interval $[0, t]$, and $N(a, b]$ is the number of events in the interval $(a, b]$. We say that a counting process $N(t)$ is a HPP if the following conditions hold.

1. $N(0) = 0$.
2. For every $a < b \leq c < d$, the random variables $N(a, b]$ and $N(c, d]$ are independent. This is called *independent increments*.
3. $\lim_{\Delta t \rightarrow 0} P(N(t, t + \Delta t] \geq 1) / \Delta t = \lambda$. The constant λ is called the *intensity* of the process.
4. $\lim_{\Delta t \rightarrow 0} P(N(t, t + \Delta t] \geq 2) / \Delta t = 0$. This assumption precludes simultaneous failures.

Under these conditions, it follows that $N(a, b]$ has a Poisson distribution with mean $\lambda(b - a)$, and the times between failures have independent exponential distributions with mean $1/\lambda$. The Poisson process is not a particularly reasonable model for repairable systems because it does not allow for either reliability improvement or deterioration.

If we replace assumption (3) above with the assumption

$$\lim_{\Delta t \rightarrow 0} \frac{P(N(t, t + \Delta t] \geq 1)}{\Delta t} = \lambda(t),$$

we are in effect allowing the probability of failure in a small interval to depend on the age of the system. The process obtained in this way is called the nonhomogeneous Poisson process (NHPP) and the function $\lambda(t)$ is called the *intensity function*. It can be shown that $N(a, b]$ has a Poisson distribution whose mean is $\int_a^b \lambda(t) dt$.

Various assumptions can be made about the functional form of $\lambda(t)$. Cox and Lewis[8] studied the NHPP with intensity

$$\lambda(t) = \exp(a + bt).$$

A more common form is

$$\lambda(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1}.$$

The NHPP obtained with this intensity function is called the *power law process* (PLP). Notice that the functional form of the intensity is identical to that of the hazard function of the Weibull distribution. The interpretations of the intensity and the hazard are completely different, however. The intensity is the instantaneous probability of a failure (any failure) of the system. The hazard is the instantaneous probability of the one and only failure of the system conditioned on survival up to that point. Because the PLP has an intensity function that is identical to the Weibull's hazard, the power law process was for a time called the *Weibull process*. Since there is a risk of confusing the Weibull distribution with the Weibull process, the term "power law process" is preferred over "Weibull process."

If $\beta > 1$, then the PLP has an increasing intensity function, indicating deterioration, since the failures tend to get closer together. If $\beta < 1$, then the PLP has a decreasing intensity, indicating reliability improvement. If $\beta = 1$, then the PLP reduces to the HPP with rate $1/\theta$.

The mean number of failures in $[0, t]$ is then

$$\Lambda(t) = E(N(t)) = \int_0^t \frac{\beta}{\theta} \left(\frac{y}{\theta} \right)^{\beta-1} dy = \left(\frac{t}{\theta} \right)^{\beta}.$$

Dividing by t and taking the log yields

$$\begin{aligned} \log \frac{\Lambda(t)}{t} &= (\beta - 1) \log t - \beta \log \theta \\ &= \alpha_0 + \alpha_1 \log t, \end{aligned}$$

where $\alpha_0 = -\beta \log \theta$ and $\alpha_1 = \beta - 1$. Duane [9] suggested plotting $\log [N(t_i)/t_i]$ (on the vertical axis) and $\log t_i$ (on the horizontal axis) in what became known as a *Duane plot*. It might seem that the PLP implies a linear Duane plot and vice versa. Neither implication, however, is true. Rigdon [10] showed that the PLP does not imply a linear Duane plot, and a linear Duane plot does not imply a PLP.

Suppose now that we have observed data from a failure process and we would like to estimate the parameters θ and β in the PLP. We consider two ways of collecting data from a repairable system. Data are said to be *failure truncated* if the observation of the repairable system was terminated after a fixed number, n , of failures. Data are said to be *time truncated* if the observation of the repairable system was terminated at a fixed time T . Point estimation, interval estimation, and hypothesis tests are somewhat different for these two kinds of truncation. (Note that we use the term truncation when referring to data collection for a repairable system, and censoring when we have a nonrepairable system.) When data are failure truncated, the number of failures, n , is fixed, but the time that testing stops, T_n , is a random variable. Conversely, when the data are time truncated, the number of failures, N , is random and the time that testing stops, T , is fixed.

When the data are failure truncated, the maximum likelihood estimators (MLEs) of the parameters are

$$\hat{\beta} = \frac{n}{\sum_{i=1}^{n-1} \log \left(\frac{t_n}{t_i} \right)}$$

and

$$\hat{\theta} = \frac{t_n}{n^{1/\hat{\beta}}}.$$

The random variable $2n\beta/\hat{\beta}$ is a pivotal quantity, having a chi-square distribution with $2(n-1)$ degrees of freedom, so a confidence interval for β is

$$\left(\frac{\chi_{1-\alpha/2}^2 (2(n-1)) \hat{\beta}}{2n}, \frac{\chi_{\alpha/2}^2 (2(n-1)) \hat{\beta}}{2n} \right).$$

Hypothesis tests for β can also be developed from this pivotal quantity. If we test $H_0: \beta = \beta_0$ against a two-sided alternative, we would reject H_0 for

$$\hat{\beta} < \frac{2n\beta_0}{\chi_{\alpha/2}^2 (2(n-1))} \text{ or } \hat{\beta} > \frac{2n\beta_0}{\chi_{1-\alpha/2}^2 (2(n-1))}.$$

Since $\beta = 1$ reduces the PLP to the HPP, we are often interested in testing $H_0: \beta = 1$.

Finkelstein [11] showed that the statistic $W = (\hat{\theta}/\theta)^\beta$ is also a pivotal quantity. Tables from Finkelstein can then be used to get a confidence interval for θ . Exact goodness-of-fit tests can be constructed from the result that, conditioned on $T_n = t_n$, the random variables

$$U_i = \log \left(\frac{t_n}{T_{n-i}} \right), i = 1, 2, \dots, n-1$$

are distributed as $n-1$ order statistics from an exponential distribution with mean $1/\beta$. Thus, any goodness-of-fit test for the exponential distribution with unknown mean can be used to test fit for the PLP. See Ref. 12 for a study of various goodness-of-fit tests, including estimates of the power.

When the data are time truncated with truncation time T , the MLEs are

$$\hat{\beta} = \frac{N}{\sum_{i=1}^N \log \left(\frac{T}{t_i} \right)}$$

and

$$\hat{\theta} = \frac{T}{N^{1/\hat{\beta}}}.$$

The random variable $2n\beta/\hat{\beta}$ is a pivotal quantity, that has a chi-square distribution with $2n$ degrees of freedom. A confidence interval for β is thus

$$\left(\frac{\chi_{1-\alpha/2}^2(2n)\hat{\beta}}{2n}, \frac{\chi_{\alpha/2}^2(2n)\hat{\beta}}{2n} \right).$$

Hypothesis tests for β can also be developed. If we test $H_0: \beta = \beta_0$ against a two-sided alternative, we would reject H_0 for

$$\hat{\beta} < \frac{2n\beta_0}{\chi_{\alpha/2}^2(2n)} \text{ or } \hat{\beta} > \frac{2n\beta_0}{\chi_{1-\alpha/2}^2(2n)}.$$

Goodness-of-fit tests can also be developed for the time-truncated case. See Refs 3 and 12 for details.

Bayesian inference procedures for the PLP were developed by Calabria *et al.* [13] and Bar-Lev *et al.* [14].

When we have data from multiple repairable systems, as in Example 5 from a

previous section, inference for the parameters depends on what assumptions we are willing to make about the similarity of the systems. If we have k systems, the possibilities include the following:

1. The k systems are identical. The only two parameters to estimate are θ and β .
2. The k systems are entirely different. We would then estimate θ_j and β_j for each system, $j = 1, 2, \dots, k$.
3. The k systems have the same β parameter, but different θ_j s.
4. The k systems have the same β parameter, but different θ_j s, where the θ_j s come from some prior distribution. This leads to an empirical Bayes model.
5. The k systems have different parameters, but the β_j s and the θ_j s each come from some prior distribution.

Details of inference procedures can be found in Ref. 3, Chapter 5.

REPAIRABLE SYSTEMS: OTHER MODELS

There are a number of other models that can be used for repairable systems.

Sen and Bhattacharyya [15] and Sen [16] proposed the piecewise exponential (PEXP) model. This model assumes that the times between failure are independent exponential random variables having means

$$E(X_i) = \frac{\delta}{\mu} i^{\delta-1}.$$

The times between failure are therefore, not identically distributed unless $\delta = 1$, in which case the PEXP reduces to the HPP. In the PEXP model with $\delta > 1$ the expected times between failures are increasing, indicating reliability improvement; however in the PEXP model, this improvement occurs at the times of failure, whereas with the PLP, or any other NHPP, the improvement is continuous. In the context of test-analyze-and-fix (TAAF), when system improvements are made when an item fails, the PEXP model may be more realistic.

Lakey and Rigdon [17] and Black and Rigdon [18] studied a model suggested by Berman [19] for repairable systems. This model is called the *modulated power law process* (MPLP). Suppose that “shocks” occur to a system according to a PLP, but a failure occurs, not at every shock but at every κ th shock, where κ is a positive integer. Under an NHPP, a repair brings the condition of the system to where it was just before the failure; for this reason, the NHPP is known as a bad-as-old, or same-as-old, model. By contrast, if the renewal process governs the failure times, then a failed/repared unit is in like-new condition. The renewal process is a good-as-new, or same-as-new, model. The MPLP is thus a compromise between the good-as-new and bad-as-old models. If $\kappa > 1$, then a failure/repair brings the system back to a condition better than it was just before the failure (because the shock counter gets reset), but not necessarily as good as a new system. The likelihood function turns out to be a valid likelihood if $\kappa > 0$, even if κ is not a positive integer, although in this case the model is harder to interpret. Inference procedures, including point and interval estimates of the three parameters, κ , β , and θ , are given in Ref. 18.

Doyen and Gaudoin [20] developed two models that are also considered a compromise between the good-as-new (renewal process) and the bad-as-old (NHPP) models. One model assumes that at the time of failure/repair, the intensity is reduced by a constant multiple, but not as far as it would be if it were renewed. Thus, a failed unit is better than just before the failure, but not as good as a new one. This model is called the *arithmetic reduction in intensity* (ARI) model. The second model reduces the “virtual age” of the system at the time of the failure by a fixed factor. This model is called the arithmetic reduction of age (ARA) model. Inference for a single system is given in Ref. 20 and a hierarchical Bayes method for multiple systems is given in Ref. 21.

EXAMPLES REVISITED

For illustration, let us consider the five examples discussed earlier.

Example 1. For the data on unscheduled maintenance times for the USS Halfbeak, we assume the PLP. The estimates (MLEs) of β and θ are

$$\hat{\beta} = \frac{71}{\sum_{i=1}^{n-1} \log\left(\frac{25518}{t_i}\right)} \approx 2.760$$

and

$$\hat{\theta} = \frac{25518}{71^{1/2.760}} \approx 5447.3.$$

The 95% confidence interval for β is

$$\left(\frac{\chi_{0.975}^2(2(71-1)) 2.760}{2 \times 71}, \frac{\chi_{0.025}^2(2(71-1)) 2.760}{2 \times 71} \right)$$

or

$$(2.122, 3.395),$$

an interval that clearly excludes 1. Thus $\beta = 1$ is not a plausible value, so we conclude that there is deterioration in the system.

Example 2. Table 3 gives the failure times of a copy machine. Here, time is measured in numbers of copies made, which is a discrete measure, although the numbers are reported to such precision that we will take these as continuous measures. Again, assuming a PLP, we have estimates

$$\hat{\beta} = \frac{18}{\sum_{i=1}^{n-1} \log\left(\frac{196,844}{t_i}\right)} \approx 1.081$$

and

$$\hat{\theta} = \frac{196,844}{18^{1/1.081}} \approx 13,571.$$

A 95% confidence interval for β is (0.595, 1.560) which includes 1. There is no evidence of reliability improvement or deterioration.

Example 3. Consider now Balaban’s data. Here the exact failure times are unknown and we only know the operating time and the number of failures that occurred in each

interval. The observed data are then the number of failures N_i , $i = 1, 2, \dots, 10$. Under the PLP, these random variables are independent (but not identically distributed) and have distribution

$$\begin{aligned} N_i &\sim \text{POISSON} \left(\int_{t_{i-1}}^{t_i} \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1} dt \right) \\ &= \text{POISSON} \left(\left(\frac{t_i}{\theta} \right)^\beta - \left(\frac{t_{i-1}}{\theta} \right)^\beta \right), \end{aligned}$$

where t_i represents the right end point of the i th interval and $t_0 = 0$. The likelihood function is thus the product of Poisson likelihoods

$$L(\beta, \theta) = \prod_{i=1}^{10} \frac{1}{n_i!} \left[\left(\frac{t_i}{\theta} \right)^\beta - \left(\frac{t_{i-1}}{\theta} \right)^\beta \right]^{n_i}$$

$$\begin{aligned} &\times \exp \left[- \left(\frac{t_i}{\theta} \right)^\beta + \left(\frac{t_{i-1}}{\theta} \right)^\beta \right] \\ &= \left(\prod_{i=1}^{10} \left[\left(\frac{t_i}{\theta} \right)^\beta - \left(\frac{t_{i-1}}{\theta} \right)^\beta \right]^{n_i} \right) \\ &\times \exp \left[- \left(\frac{t_n}{\theta} \right)^\beta \right] \left(\prod_{i=1}^{10} n_i! \right)^{-1}. \end{aligned}$$

The logarithm of this likelihood can then be maximized using numerical methods. A contour plot of the log-likelihood function is shown in Fig. 6. The MLEs, found by numerically optimizing the log-likelihood function, are

$$\hat{\beta} = 0.5901 \text{ and } \hat{\theta} = 77.70.$$

Asymptotic 95% confidence intervals for β and θ , obtained using the observed Fisher information matrix, are

$$(0.5067, 0.6735)$$

and

$$(16.87, 138.5),$$

Figure 6. Contour plot for log-likelihood for Balaban's data.

Figure 7. Jelinski and Moranda [5] software data.

respectively. Here, the confidence interval for β contains only values of β that are less than one, indicating reliability improvement.

Example 4. Next, consider the Jelinski and Moranda data on software failures. The data from Table 6 are shown in Fig. 7, where cumulative operating time is plotted against cumulative number of failures. This figure shows that initially failures occur at roughly a constant rate (approximately 20 per hundred hours). After about 100 h, the pattern of failures is much more erratic. When modeling software, we must take into account the existence of “bugs” in the system, and testing is designed to find the bugs. The reader is referred to Ref. 5 for a more detailed analysis of this data.

Example 5. Finally, consider the data from Table 5 which gives the failure times of 41 valves. Note that 17 out of the 41 valves had no failures at all, and the most failures on any system was four. With the paucity of data, we assume that the systems are identical and that the failure times are governed by a time-truncated PLP. The MLEs of β and θ are

$$\hat{\beta} = 1.420$$

and

$$\hat{\theta} = 548.9.$$

A 95% confidence interval for β is (1.070, 1.890), giving (marginal) evidence of reliability deterioration.

RESOURCE MODELING ASSOCIATION

STEVEN MCKELVEY
Professor of Mathematics and
Computer Science, Center for
Integrative Studies, St. Olaf
College, Northfield, Minnesota

The Resource Modeling Association (RMA) was conceived of and founded in the early 1980s by Dr. Roland Lamberson of Humboldt State University and Dr. Robert McKelvey of the University of Montana. Working closely together, these scientists recruited a group of applied mathematicians, applied population biologists, fisheries scientists, and resource economists, primarily from the west coast of North America, to participate in annual meetings to discuss the application of models to resource management. Over the years, the RMA has grown into a truly international professional society with active members from throughout the world. North America, Europe, and Asia are particularly well represented.

The goals of this broadly interdisciplinary research-oriented society are to discuss and exhibit exemplary applications of modeling technology to questions of natural resource management. Here “natural resource” is understood in its broadest meaning, with an emphasis on renewable resources. Particular issues of concern to the society are the effects of global warming on natural resources, the creation and design of ecological preserves, population dynamics, sustainable development, the appropriate use of models in policy formulation, and water use policy.

A secondary goal of the association is to create and demonstrate professional standards for the articulation of key ideas in the design, implementation, and application of mathematical models to problems involving natural resources. In the early days of the society, the mechanisms for presenting models and their results in a

scholarly acceptable fashion were unclear. Clear standards existed for the presentation of theoretical analyses of mathematical constructs and equally clear standards existed for the presentation of quantitative results of field studies. In the early 1980s, it was not so clear how mathematical models and their results ought to be presented. A typical model would possess certain mathematical properties, equilibria of various types, chaotic behavior, quantifiable asymptotic behavior, and so on: important qualities to elucidate in professional articles. However, it was not so clear how to present the results of these models when they were applied to important “real-world” situations. The usual statistical analyses seemed inappropriate as the quantities being analyzed were not truly random in nature, but were the result of either a deterministic model or a pseudorandom computation.

This confusion, which continues today in the cases of newer styles of models such as individual-based models, is a significant issue for scholars pursuing work in the modeling field. The RMA has played, and continues to play, a key role in defining and promulgating professional standards for the description, application, and analysis of mathematical models involving natural resource issues.

The society seeks to meet its goals through two main activities: hosting an annual world conference on Natural Resource Modeling and the publication of the scholarly journal *Natural Resource Modeling* (Wiley-Blackwell), a quarterly, peer reviewed professional publication.

The RMA strives to support early career researchers in the various subdisciplines of natural resource modeling. Members are typically active in several professional organizations and the RMA seeks to nurture its members’ professional development as a way to strengthen their individual research work and visibility as well as to support the growth and strength of the RMA itself.

The society’s journal, *Natural Resource Modeling* (NRM), takes special efforts,

beyond the simple return of reviewers' comments, to work with authors to strengthen their writing and organizational skills to ensure a productive publication career into the future. If desired by an author, the NRM's editorial staff is willing to engage in extensive discussions with the author about a submitted paper and changes in the work that would result in a stronger presentation. This detailed and personal feedback, useful for any author, is particularly valuable for those early in their publication career and seeking to establish a solid presence in the profession.

The RMA's annual meeting, the World Conference on Natural Resource Modeling (WCNRM), is designed to be inviting and accessible to scholars at all points in their careers. The recent practice has been to hold meetings in North America in odd-numbered years and outside North America in even-numbered years. The meetings are typically held in locations with some connection to issues in natural resource management. Great care is taken to use inexpensive accommodations and meeting facilities, often university classrooms and residence halls, to keep meeting expenses as reasonable as possible. Paper presentations are organized to avoid parallel sessions, giving the entire membership a chance to hear papers representing a wide variety of perspectives.

The meetings are scientifically serious, representing cutting edge research in all areas of natural resource modeling. Contributed papers are screened by a science committee before acceptance onto the meeting program. At the same time, the social atmosphere of meetings is quite informal, with ample opportunities to meet and chat with other members, cementing bonds that persist past the meeting's close. It is a WCNRM tradition to incorporate an afternoon educational excursion to a nearby location of particular natural beauty or historical interest. It is also frequent practice for the hosts of the WCNRM to organize a premeeting multiday outdoor excursion of some type, be it kayaking, backpacking, or some other adventure to remind members

why they have chosen careers in the wise use and management of natural resources.

The RMA was begun in the early 1980s to promote the use and understanding of mathematical models applied to issues of natural resource management, with particular emphasis on endangered species, fisheries, and forest management on the western coast of North America. The first meeting of the society was held in 1982 at Humboldt State University in Arcata, California. The name of the conference was the First Pacific Coast Resource Modeling Conference (PCRMC). The proceedings of this meeting were published in journal form under the title *Mathematical Models of Renewable Resources*, beginning the RMA's role as a producer of scholarly publications concerning resource modeling.

As the society's membership grew, both in number and geographical breadth, the regional focus of the organization diminished. The RMA cosponsored the First Atlantic Coast Resource Modeling Conference in 1988, and in 1989 began the annual Interdisciplinary Conference on Natural Resource Modeling and Analysis (ICNRMA). The latter drew scientists from around the world and established the RMA as an international presence in the scholarly development, application, and analysis of natural resource models.

In 1994, the decision was made to consolidate these meetings into a single international conference. The first RMA WCNRM was held in 1995 in the Republic of South Africa. These world meetings continue, alternating between North American sites and sites on other continents. Aside from South Africa, the WCNRM has been held in the United States, Canada, Norway, Poland, Spain, Italy, England, Australia, Greece, the Netherlands, and Mexico.

The society's peer reviewed journal, *Natural Resource Modeling* (NRM), succeeded the proceedings of the PCRMC in 1986. The scholarly content of NRM is controlled by an editor and editorial board chosen by the RMA. The actual publication of the journal was undertaken by the Rocky Mountain Mathematics Consortium. The journal grew in both circulation and scholarly reputation.

In 2008, publication rights to the journal were transferred to Wiley-Blackwell. The RMA continues to exercise editorial control of the journal's content. The journal's contents are included in the listings created by Science Citation Index.

The association is a not for profit 501(c)(3) corporation which is incorporated under the laws of South Carolina. It is governed by a Board of Directors comprising four officers and five at-large directors. The President, the Vice President, and the five at-large members of the board are elected directly by the membership. The remaining two officers, the Secretary, and the Treasurer, are nominated by the President and elected by the board. The terms of office for the President, Secretary, and Treasurer is two years. The Vice President's position is filled by either the President-Elect (1 year) or the most recent Past President (1 year), allowing for an overlap in leadership and the preservation of institutional memory.

An Executive Secretary is also an important part of the RMA's leadership. This position carries an indeterminate length and is occupied by a long standing active member of the organization. The Executive Secretary is the public face of the organization, answering queries from the general public and providing important advice for the current officers and directors. The Executive Secretary serves at the pleasure of the Board

of Directors for whatever term the Board feels is advisable.

Lastly, the association has established an honorary title which is given, rarely, to members whose service to the RMA and the broader modeling community has been truly exceptional. RMA Fellows are elected from time to time by the Board of Directors. It is an honor given infrequently, having been given five times in the first 25 years of the RMA's existence.

Since its inception, the RMA's leadership reflects the diversity of its membership, both scholarly and geographically. The list of past Presidents includes: Roland Lamberson (Humboldt State University, 1982–1988), Robert McKelvey (University of Montana, 1989–1990), Colin Clark (University of British Columbia, 1991–1992), John Beddington (Imperial College London, 1993–1994), Wayne Getz (University of California—Berkeley, 1995–1996), Gordon Swartzman (University of Washington, 1997–1998), John Hearne (University of Natal, South Africa, 1999–2000), Anthony Charles (Dalhousie University, Canada, 2001–2002), John Conrad (Cornell University, 2002–2004), William Smith (US Forest Service, 2004–2006), Robert Fray (Furman University, 2006–2008), Steven McKelvey (St. Olaf College, 2008–2010), Keith Cridle, (University of Alaska—Fairbanks, 2010–2011).

RETRIAL QUEUES

JESÚS R. ARTALEJO
Faculty of Mathematics,
Complutense University of
Madrid, Madrid, Spain

INTRODUCTION

Retrial queues consist of a service facility and a pool of unsatisfied customers, called the *orbit*. Customers who cannot receive service leave the service area but they may join the orbit and reattempt for service after some random time. The general mechanism of a retrial queue is shown schematically in Fig. 1. The following motivating examples illustrate some situations that can be modeled as retrial queues.

Example A. Telephone Systems. A telephone subscriber, who obtains a busy signal repeats the call until the demand is satisfied. As a result, the total flow of calls circulating in a telephone network is integrated by the superposition of the flow of primary calls, which reflects the real wishes of the telephone subscribers, and the flow of repeated calls, which is the consequence of the lack of success of previous attempts.

Example B. Random Access Protocols in Communication Networks. Consider a communication line with slotted time which is shared by several stations. If two or more stations are transmitting packets simultaneously, then a collision takes place. As a result, all the involved packets are destroyed and must be retransmitted. The stations would try to retransmit in the nearest slot, but then a collision occurs with certainty. To avoid this, each station independently of the other stations involved in the conflict, may either retransmit the packet with probability p or delay actions until the next slot with probability $1 - p$. In other words, each station

introduces a random delay before the next attempt to transmit the packet.

Example C. Daily Life Situations. We often observe that a person finding a long waiting line prefers to balk and return later. A similar behavior is demonstrated by those impatient customers, who initially entered the line, but they abandon when their patience expires.

In these examples, the access from the orbit to the service facility is governed by the classical retrial policy, where each blocked customer (or unit) retries independently of the rest of customers in the orbit. The literature also includes a few applications operating under other generalized retrial policies. Most retrial queues arise from computer and communication applications, where the repeated attempts occur due to blocking in a system with limited service capacity. This is the case of Examples A and B. In contrast, Example C illustrates the case where the retrial phenomenon is caused by balking or impatience. We also mention the existence of models where retrials are due to breakdowns of the unreliable servers [1].

Apart from their practical applications, the retrial queues raise interesting mathematical problems. Because of the retrial feature, the underlying stochastic process that represents the state of the system is not space-homogeneous. This creates severe analytical problems and allows explicit formulae only in a few special cases. By contrast, the retrial literature is rich in approximation and numerical methods.

Among the vast literature in retrial queues, the existence of two specific books needs to be noted. The monograph by Falin and Templeton [2] provides an excellent account of analytical results for the basic $M/M/c$ and $M/G/1$ retrial queues and some extensions. On the other hand, the main focus of the book by Artalejo and Gomez-Corral [3] is on the application of approximate techniques and algorithmic methods for solving the analytically intractable retrial queues.

Figure 1. General structure of a retrial queue.

For an overview of the standard $M/M/c$ and $M/G/1$ queues without retrials, we refer to the articles titled *The M/M/s Queue* and *The M/G/1 Queue* in this encyclopedia.

THE BASIC MODELS AND THEIR SOLUTION

In this section, we describe the $M/M/c$ and $M/G/1$ retrial queues and summarize some natural variants and extensions.

We consider a multiserver queue to which primary customers arrive according to a Poisson process with rate λ . Service is rendered by c identical servers with service times exponentially distributed with rate ν . The service facility does not have a waiting space. Customers who find at least one server free upon arrival immediately occupy a position and leave the system after service. In contrast, any arriving customer finding all servers busy will enter the orbit. From there, the retrial customers will compete for service. The inter-retrial times are assumed to be exponentially distributed with rate μ . Moreover, we assume that the process of primary arrivals, services, and retrial times are mutually independent.

At any time t , the state of the process is represented by the bidimensional process $(C(t), N(t))$, where $C(t)$ is the number of busy servers and $N(t)$ denote the number of customers in an orbit. The process $\{(C(t), N(t)); t \geq 0\}$ is an irreducible, regular, continuous-time Markov chain with space state $S = \{0, 1\} \times \{0, 1, \dots\}$. Figure 2 illustrates the transitions among the states for the case $c = 3$. Its infinitesimal transition rates $q_{(i,j),(m,n)}$ are as follows. For

Figure 2. State space and transitions.

$0 \leq i \leq c - 1$, we have

$$q_{(i,j),(m,n)} = \begin{cases} \lambda, & \text{if } (m,n) = (i+1,j), \\ i\nu, & \text{if } (m,n) = (i-1,j), \\ j\mu, & \text{if } (m,n) = (i+1,j-1), \\ -(\lambda + i\nu + j\mu), & \text{if } (m,n) = (i,j), \\ 0, & \text{otherwise,} \end{cases} \quad (1)$$

and for $i = c$

$$q_{(c,j),(m,n)} = \begin{cases} \lambda, & \text{if } (m,n) = (c,j+1), \\ c\nu, & \text{if } (m,n) = (c-1,j), \\ -(\lambda + c\nu), & \text{if } (m,n) = (c,j), \\ 0, & \text{otherwise.} \end{cases} \quad (2)$$

In the $M/G/1$ retrial queue, the service distribution is generalized to follow a general law with probability distribution function $B(x)$ ($B(0) = 0$), Laplace–Stieltjes transform $\beta(s)$ and moments β_k . Now, the mathematical model can be viewed as a Markov regenerative process.

The retrial literature is rich so it is possible to find a vast number of variants

and generalizations including batch arrivals, discrete-time models, finite population, multiclass queues, nonpersistent customers, priorities, server breakdowns, and so on [3, Section 2.3]. In investigating variants, it is important to distinguish between basic properties, which follow straightforward extensions of the derivations for the basic $M/M/c$ and $M/G/1$ retrial queues, and specific significant properties of each extended model. Here, we point out the important role played by the matrix-analytic formalism, which provides useful tools to analyze many retrial queues with structured Markov chains (QBD , $GI/M/1$ and $M/G/1$ structures) [3, Chapters 7–9]. In particular, the Markovian arrival process (MAP) extends the Poisson process allowing the correlation between arrivals. On the other hand, the distributions of phase-type (PH) generalize the exponential law, but keeping many interesting properties and without losing computational tractability.

LIMITING DISTRIBUTION OF THE SYSTEM STATE

To ensure the existence of a steady-state distribution, we assume that $\rho = \lambda/cv < 1$ ($M/M/c$ retrial queue) and $\rho = \lambda\beta_1 < 1$ ($M/G/1$ retrial queue). Then, the limiting probabilities $p_{ij} = \lim_{t \rightarrow \infty} P\{C(t) = i, N(t) = j\}$, for $0 \leq i \leq c$ and $j \geq 0$, exist and they are positive.

The limiting probabilities for the $M/M/1$ retrial queue are given by

$$p_{0j} = \frac{\rho^j}{j! \mu^j} (1 - \rho)^{1 + \frac{\lambda}{\mu}} \prod_{k=0}^{j-1} (\lambda + k\mu), \quad j \geq 0, \quad (3)$$

$$p_{1j} = \frac{\rho^{j+1}}{j! \mu^j} (1 - \rho)^{1 + \frac{\lambda}{\mu}} \prod_{k=1}^j (\lambda + k\mu), \quad j \geq 0, \quad (4)$$

and the partial factorial moments $M_k^i = \sum_{j=k}^{\infty} j(j-1)\dots(j-k+1)p_{ij}$, for $i = 1, 2$

and $k \geq 0$, are

$$M_k^0 = (1 - \rho) \left(\frac{\rho}{\mu(1 - \rho)} \right)^k \prod_{j=0}^{k-1} (\lambda + j\mu), \quad k \geq 0, \quad (5)$$

$$M_k^1 = \rho \left(\frac{\rho}{\mu(1 - \rho)} \right)^k \prod_{j=1}^k (\lambda + j\mu), \quad k \geq 0. \quad (6)$$

In the case $c = 2$, the limiting probabilities can be expressed in terms of hypergeometric functions. No explicit formulae for p_{ij} are obtained for the case $c \geq 3$. However, we have the following mean values:

$$E[C] = \frac{\lambda}{v}, \quad (7)$$

$$E[N] = \frac{(v + \mu)(\lambda - v \text{Var}(C))}{\mu(cv - \lambda)}, \quad (8)$$

where C and N denote the steady-state number of busy servers and customers in orbit, respectively. Although an explicit formula for $\text{Var}(C)$ is unknown, formula (8) reduces the computation of $E[N]$ to the variance of the number of busy servers, which could be easily estimated.

A number of interesting theoretical papers are devoted to the analytical solution of the model with an arbitrary number of servers. Since the stationary distribution of the system state is expressed in terms of contour integrals or as limit of extended continued fractions, it is not convenient for practical purposes. More useful is the implementation of approximations and truncated models. This investigation can be classified along three broad lines: approximations, finite truncated models, and generalized truncated models [3, Section 3.4].

The following formulae provide a recursive scheme for the computation of the limiting

probabilities in the $M/G/1$ retrial queue:

$$p_{0j} = \frac{\lambda}{\lambda + j\mu} \pi_j, \quad j \geq 0, \quad (9)$$

$$p_{1j} = \frac{(j+1)\mu}{\lambda} p_{0,j+1}, \quad j \geq 0, \quad (10)$$

$$\pi_j = \sum_{i=0}^j \pi_i \frac{\lambda}{\lambda + i\mu} a_{j-i} + \sum_{i=1}^{j+1} \pi_i \frac{i\mu}{\lambda + i\mu} a_{j-i+1}, \quad j \geq 0, \quad (11)$$

$$\pi_0 = (1 - \rho) \exp \left\{ -\frac{\lambda}{\mu} \int_0^1 \frac{1 - \beta(\lambda - \lambda u)}{\beta(\lambda - \lambda u) - u} du \right\}, \quad (12)$$

where $a_j = \int_0^\infty e^{-\lambda t} \frac{(\lambda t)^j}{j!} dB(t)$, for $j \geq 0$, is the probability that exactly j customers arrive during a service time. The sequence $\{\pi_j; j \geq 0\}$ corresponds to the distribution of the embedded Markov chain at service completion epochs.

The two first partial factorial moments are given by

$$M_0^0 = 1 - \rho, \quad (13)$$

$$M_0^1 = \rho, \quad (14)$$

$$M_1^0 = \frac{\lambda\rho}{\mu}, \quad (15)$$

$$M_1^1 = \frac{\lambda^2\beta_2}{2(1-\rho)} + \frac{\lambda\rho^2}{\mu(1-\rho)}, \quad (16)$$

$$M_2^0 = \frac{\lambda}{\mu} M_1^1, \quad (17)$$

$$M_2^1 = \frac{\lambda^3\beta_3}{3(1-\rho)} + \frac{\lambda^4\beta_2^2}{2(1-\rho)^2} + \frac{3\lambda^3\rho\beta_2}{2\mu(1-\rho)^2} + \frac{\lambda^2\rho^3}{\mu^2(1-\rho)^2}. \quad (18)$$

WAITING TIME

We now consider the waiting time, $W(t)$ of a customer who arrives at the system at time t . According to this definition, $W(t)$ means the time that the customer spends waiting at the orbit excluding the service time. We assume that the system has reached the steady-state regime. Then, $W(t)$ is replaced by W , which denote the steady-state spent in orbit. The

distribution of W depends on the service discipline. Retrial queues arising from teletraffic applications operate under a random order access discipline. Random servicing is complicated due to the overtaking phenomena; that is, it is necessary to consider not only the number of customers present in the system at the time of arrival of a customer whose delay is to be investigated, but also the possibility that customers arriving at a later time will compete for free servers.

The waiting time of the $M/M/c$ retrial queue can be approximated by employing the truncated model with finite orbit capacity [3, Section 5.2.1].

For the waiting time of the $M/G/1$ retrial queue with random order of service, the Laplace–Stieltjes transform of W is given by Falin and Templeton [2, Section 1.8]

$$W^*(s) = 1 - \rho + \frac{\lambda(1-\rho)}{s} \int_{L_\infty^*(s)}^1 \frac{(1-u)(\beta(\lambda - \lambda u) - \beta(s + \lambda - \lambda u))}{(\beta(\lambda - \lambda u) - u)(u - \beta(s + \lambda - \lambda u))} \times \exp \left\{ \frac{1}{\mu} \int_u^1 \left(\frac{s + \mu + \lambda - \lambda v}{\beta(s + \lambda - \lambda v) - v} - \frac{\lambda - \lambda v}{\beta(\lambda - \lambda v) - v} \right) dv \right\} du, \quad (19)$$

where $L_\infty^*(s) = \beta(s + \lambda - \lambda L_\infty^*(s))$ is the Laplace–Stieltjes transform of the busy period in the standard $M/G/1$ queue without retrials.

The mean waiting time can be easily obtained with the help of Little's formula:

$$E[W] = \frac{E[N]}{\lambda} = \frac{\lambda\beta_2}{2(1-\rho)} + \frac{\rho}{\mu(1-\rho)}. \quad (20)$$

A direct method of calculation for the second moment yields

$$E[W^2] = \frac{2\lambda\beta_3}{3(1-\rho)(2-\rho)} + \frac{\lambda^2\beta_2^2}{(1-\rho)^2(2-\rho)} + \frac{\lambda\beta_2}{\mu} \left(\frac{2}{(1-\rho)^2(2-\rho)} + \frac{\rho}{(1-\rho)^2} \right) + \frac{2\rho}{\mu^2(1-\rho)^2}. \quad (21)$$

Unfortunately, it does not seem possible to numerically invert the density function of W because the above solution from Equation (19) is derived when s is a real number, but algorithmic methods of numerical inversion typically require evaluation of the Laplace–Stieltjes transform at any desired complex s . In Ref. 3, Section 5.1.1, maximum entropy, truncated and gamma approaches are discussed for the approximate analysis of W in the $M/G/1$ retrial queue.

OTHER PERFORMANCE DESCRIPTORS

The limiting distribution of the system state and the waiting time are the most extensively studied characteristics in queueing theory. However, many other performance descriptors are also of interest. In this section, we collect some results about the length of the busy period, the number of customers served, the number of retrials made by a customer, and the maximum orbit length.

For the study of other, more specific descriptors such as the number of attempts since the last service completion, the successful and blocked events, the server idle periods, and the time to reach a certain orbit limit, the reader is referred to the material in Ref. 3, Chapter 6.

Length of the Busy Period

The busy period of a retrial queue, L , is defined as the elapsed time starting with the arrival of a primary customer, finding an empty system, and ending at the first service completion epoch at which the system is empty again. In the case of the $M/M/c$ retrial queue, the algorithmic analysis of the length of the busy period and computation of its moments can be based on the generalized truncated models [3, Section 4.2.1]. In what follows, we summarize the main explicit results for the $M/G/1$ retrial queue.

The Laplace–Stieltjes transform of L in the $M/G/1$ retrial queue is given by the

following equation [2, Section 1.6]:

$$L^*(s) = \frac{\int_0^{L_\infty^*(s)} \frac{\beta(s + \lambda - \lambda u)}{e(s, u)(\beta(s + \lambda - \lambda u) - u)} du}{\int_0^{L_\infty^*(s)} \frac{du}{e(s, u)(\beta(s + \lambda - \lambda u) - u)}}, \quad s > 0, \quad (22)$$

where $e(s, u)$ is

$$e(s, u) = \exp \left\{ \frac{1}{\mu} \int_0^u \frac{s + \lambda - \lambda \beta(s + \lambda - \lambda v)}{\beta(s + \lambda - \lambda v) - v} dv \right\}, \quad 0 \leq u < L_\infty^*(s).$$

Methods based on the principle of maximum entropy and on the truncation of the orbit are still helpful for the approximate computation of the density function of L [3, Section 4.1.1].

The two first moments are

$$\begin{aligned} E[L] &= \frac{1}{\lambda} \left(\frac{1}{p_{00}} - 1 \right), \quad (23) \\ E[L^2] &= \frac{1}{p_{00}} \left(\frac{1}{(1 - \rho)^2} \left(\frac{2\rho\beta_1}{\mu} + \beta_2 \right) \right. \\ &\quad - \int_0^1 \frac{2}{\lambda\mu(\beta(\lambda - \lambda u) - u)} \\ &\quad \times \left(1 - \frac{\lambda(1 - u)\beta'(\lambda - \lambda u)}{\beta(\lambda - \lambda u) - u} - \frac{1}{1 - \rho} \right. \\ &\quad \left. \left. \times \exp \left\{ \frac{\lambda}{\mu} \int_u^1 \frac{1 - \beta(\lambda - \lambda v)}{\beta(\lambda - \lambda v) - v} dv \right\} \right) du \right). \quad (24) \end{aligned}$$

Number of Customers Served

The number of customers served, I , during a busy period is the discrete counterpart of the length of the busy period. The expectations of both characteristics are related by the simple expression $E[I] = 1 + \lambda E[L]$. The algorithmic analysis for I in the $M/M/c$ retrial queue is basically parallel to the existing approach for L .

In the case of the $M/G/1$ retrial queue, we know the following explicit formulae for the first elements of the probability mass

function:

$$P(I = 1) = a_0, \quad (25)$$

$$P(I = 2) = a_0 a_1 \frac{\mu}{\lambda + \mu}, \quad (26)$$

$$P(I = 3) = a_0^2 a_1 \frac{\lambda \mu}{(\lambda + \mu)^2} + a_0 a_1^2 \frac{\mu^2}{(\lambda + \mu)^2} + a_0^2 a_2 \frac{2\mu^2}{(\lambda + \mu)(\lambda + 2\mu)}. \quad (27)$$

A recursive scheme for the computation of the distribution function $P(I \leq k)$, for $k \geq 1$, can be found in Ref. 3, Section 4.1.2.

The two first moments are given by

$$E[I] = \frac{1}{p_{00}}, \quad (28)$$

$$E[I^2] = \frac{1}{p_{00}} \left(\frac{1 - \rho^2 + 2\frac{\lambda}{\mu}\rho + \lambda^2\beta_2}{(1 - \rho)^2} + \int_0^1 \frac{2\lambda}{\mu(\beta(\lambda - \lambda u) - u)} \times \left(\frac{1}{1 - \rho} \times \exp \left\{ \frac{\lambda}{\mu} \int_u^1 \frac{1 - \beta(\lambda - \lambda v)}{\beta(\lambda - \lambda v) - v} dv \right\} - \frac{(1 - u)\beta(\lambda - \lambda u)}{\beta(\lambda - \lambda u) - u} \right) du \right). \quad (29)$$

Number of Retrials Made by a Customer

The number of retrials made by a customer before entering service, R , is the natural discrete counterpart of W . The distribution of this descriptor has been investigated in Ref. 3, Sections 5.1.2 and 5.2.2, for the truncated versions of the $M/M/c$ and $M/G/1$ retrial queues.

Since $W = \sum_{k=1}^R \xi_k$, where ξ_k denotes the time between k th and $(k-1)$ th retrial attempts made by an arbitrary tagged customer, we find that

$$E[R] = \mu E[W], \quad (30)$$

and, in the $M/G/1$ case, we have

$$E[R] = \frac{\rho}{1 - \rho} + \frac{\lambda \mu \beta_2}{2(1 - \rho)}. \quad (31)$$

Maximum Orbit Length

The maximum orbit size, $N_{\max}$, observed during a busy period is a system descriptor clearly connected to the system congestion. Its algorithmic analysis can be performed for the original $M/M/c$ and $M/G/1$ retrial queues with infinite orbit capacity [3, Sections 4.1.3 and 4.2.3].

In the $M/M/1$ retrial queue, the distribution of $N_{\max}$ has the following explicit expression:

$$P(N_{\max} \leq k) = \frac{\sum_{m=0}^k \frac{m!}{\rho^m \prod_{n=1}^m \left(\frac{\lambda}{\mu} + n \right)}}{\rho + \sum_{m=0}^k \frac{m!}{\rho^m \prod_{n=1}^m \left(\frac{\lambda}{\mu} + n \right)}}, \quad k \geq 0. \quad (32)$$

FURTHER READING

Many textbooks include chapters or sections devoted to retrial queues [4–11] and for a general survey of the main retrial features and literature, the reader is referred to the review papers [12–15]. More concretely, the papers by Falin [12,13] provide a general overview not only of the main models but also of many variants. Yang and Templeton [15] focus on the embedded Markov chain technique and the stochastic decomposition property. The paper by Kulkarni and Liang [14] emphasizes the stochastic monotonicity and optimal control problems. Artalejo and Falin [16] concentrate on the comparative analysis between standard and retrial queues. Finally, Refs 17–19 give bibliographical information.

REVENUE MANAGEMENT IN THE TRAVEL INDUSTRY

WARREN LIEBERMAN
Veritec Solutions Belmont,
California

Yield Management¹ could easily turn out to be the most important pricing breakthrough of the 20th Century—Professor James Makens, Wake Forest University [1]
... look to yield management at the airlines as the model for future pricing in fields as diverse as health care, telecommunications, consumer financial services, insurance, hotels and government services. Yield management techniques will rewrite the supply-and-demand equations that determine service availability and price [2]
[Yield Management] promises to spearhead a revolution in pricing strategies during this decade [3]
Yield Management is the single most important technical development in transportation management since we entered the era of airline deregulation in 1979—Bob Crandall, former CEO and President of AMR and American Airlines [4]²
We estimate that yield management has generated \$1.4 billion in incremental revenue in the last three year years [for American Airlines]... We expect yield management to generate at least \$500 million annually for the foreseeable future—Bob Crandall [4]
...our competitors used... Yield Management in every one of our markets, and they pushed

us straight towards bankruptcy... Where did we go wrong?... we didn't get our hands around the Yield Management—Don Burr, former CEO of People Express Airlines [5–8]
If I were in charge of the antitrust division, I would damn well see if I could build a case that yield management is predatory pricing—Alfred Kahn, former Chairman of the Civil Aeronautics Board under President Carter and known as the father of airline deregulation [9]
Yield management as it applies to airlines is the control and management of reservations inventory in way that increases (maximizes, if possible)... profitability, *given the flight schedule and fare structure*. [emphasis added] [4]
Revenue Management is the art and science of predicting real-time customer demand at the micromarket level and optimizing the price and availability of products [8].

INTRODUCTION

The methods and information used by firms in the travel industry that govern the range of products they offer for sale, the number of sales they make, and the prices they charge have undergone dramatic change in the past 30 years. As noted in the above quotes, these changes have revolutionized the travel industry and are penetrating other industries as well.

Whereas some of these decisions were once based on intelligent “rules-of-thumb,” they now draw on sophisticated mathematical models. In some cases, the advances in decision support tools in combination with advances in electronic distribution and management of inventory have enabled travel firms to offer and manage products that would not otherwise have been possible. Further, the financial gains made possible by these developments, initially known as yield management (YM) and later as revenue management (RM), have been extraordinary.

This article provides an historical overview of why and how this transformation occurred. Much of the discussion on the

¹As the practice of yield management spread beyond the airline industry, the term changed to revenue management. Except for providing background on the term's evolution, and in keeping with the title of this article, we generally refer to the discipline of forecasting customer demand and available supply in real-time and using that information to control product availability and dynamically set prices so as to maximize profits, as revenue management.

²This quote has become well known and is often cited; see, for example, Refs 8, 41.

early stages of yield management is oriented towards the airline industry, as it provided the initial setting for the early innovations—innovations that soon spread to other industries. As yield management evolved into other industries and became known as *revenue management*, the discipline broadened from optimizing capacity controls (e.g., the maximum number of sales that were allowed at previously established prices) to include pricing optimization (e.g., determining what prices should be). The latter portions of this article are oriented around the expanding practice of the discipline and its adoption by other segments of the travel industry.

Often misunderstood, yield or revenue management has now attained a prominent position among the strategies and tactics travel companies use to obtain a competitive advantage over their rivals. As might be gleaned from the quotes above, it is a relatively new way of doing business and many believe it to be an extraordinarily powerful technology. CEOs of companies that invested in it have extolled its virtues as well as its importance for achieving better financial returns. This article provides an overview of what revenue management is, how it evolved in the travel industry, and why it attracts strong interest.

FROM YIELD TO REVENUE: A HISTORICAL OVERVIEW

It is frequently suggested that the science, if not the practice of yield management originated in the US airline industry in the early 1980s, shortly after it was deregulated in 1978. In fact, the early stages of yield management date back quite a bit further, probably to the 1960s. Until 1985, however, the practice attracted limited attention, was narrow in scope, and remained within the airline industry.

For many years, it would not be unusual for 15% or more of those who purchased airline tickets to fail to show up for their flights. In part, this occurred because unused

tickets were fully refundable.³ For flights in high demand, more tickets would be sold than there were seats on the plane. Known as *overbooking*, this practice was routinely carried out by the airlines but it did not attract widespread attention until Allegheny Airlines did not allow Ralph Nader to board his flight in 1972. Nader sued Allegheny and the lawsuit eventually went to the US Supreme Court in 1976 [10]. Overbooking decisions based on mathematical models that seek to maximize financial returns subject to customer service constraints constitute a core element of many airline revenue management programs. Indeed, the first phase of revenue management essentially consisted solely of overbooking.

Until 2000 or perhaps even later, most airline yield management departments did not set prices, but rather focused on controlling the availability of reservation or seat inventory at different prices with the objective of maximizing net revenue. The actual prices at which tickets could be sold were determined by Pricing Departments. Although Yield Management had no responsibility for setting prices, it determined which fares and how many tickets at each fare could be purchased on each flight. In part, this resulted from the organizational structure of most airlines, whereby the Pricing Department and the Inventory Control or Yield Management Department, were separate.⁴ Indeed, in 1985 when American Airlines launched its Ultimate Super Savers fares—discounts of up to 70% with restrictions such as 30-days advance purchase, 7-day minimum stay, and only partially refundable—enabling the airlines to compete for passengers in radically new ways, its yield management department was not made aware of the new fares until they were announced to the public. This organizational decision resulted

³Today, the frequency with which passengers fail to show up for their flights is much less, as many of the tickets sold are nonrefundable.

⁴During the late 1990s, some airlines began to restructure their organizations, consolidating pricing and inventory functions or having these staff work in a more coordinated manner.

in significant revenue dilution. The fares stimulated so much demand, so quickly, even for flights 6–12 months in the future, that American's yield managers could not react fast enough to reset fare and booking controls on all flights to limit the sale of Ultimate Super Saver fares to appropriate levels. Seats that could have been sold to business travelers who were willing to purchase tickets at higher fares, but would not do so until closer to the date of their flight's departure, were instead occupied by those who purchased fares for up to 70% less. Many flights generated less revenue and profit than they otherwise might have.

Prior to the late 1980s and the adoption of revenue management by travel firms other than airlines, yield management decisions were essentially limited to two decisions:

- the number of reservations to accept for a flight;
- the fares, previously established by the pricing department, that should be offered for purchase to potential customers for a flight at various times prior to departure (the actual setting of fares was thus done outside of yield management; yield management only controlled which of the fares were available for purchase).

As we will soon discuss, one of the most innovative as well as revenue enhancing elements of airline yield management programs was that by introducing purchase restrictions on airline tickets—often termed fences—a

single product could be sold, simultaneously, at multiple prices.

Yield had a specific meaning in the airline industry, being related to revenue in two ways:

1. Revenue per available seat-mile or revenue per available seat-kilometer (RASM and RASK) provided a measure of revenue per unit of capacity.
2. Revenue per passenger-mile or revenue per passenger-kilometer (RPM or RPK) offered a normalized measure of fares paid.

Because the two types of reservation controls noted above had clear and direct impacts on both measures of yield, the term *yield management* seemed apt.

In the late 1980s and early 1990s, as the practice of yield management spread to hotels, car rental firms, passenger railroads, cruise lines, and other segments of the travel industry, the phrase “yield management” was often viewed as airline jargon. Other companies typically focused on revenue and profit, not yield. The term became increasingly controversial. Even as they embraced its concepts, many sought a different label for the practice of revenue maximization through inventory allocation controls.

The search for a new label may well have been accelerated by the airline industry's financial difficulties in 1990, 1991, and 1992. Table 1 highlights the financial difficulties experienced by the largest seven US airlines during these years. With some exceptions,

Table 1. Net Earnings of the Seven Largest US Airlines, 1990–1992 (\$000,000)

Airline	1990	1991	1992	Total
American Airlines	(76.8)	(165)	(735)	(976.8)
Continental Airlines	(273.8) ^a	(340.9)	(229.4)	(844.1)
Delta Air Lines	(259.4) ^b	(239.5)	(564.8)	(1,063.7)
Northwest Airlines	—	(310)	(386.2)	(696.2)
TWA Airlines	(162.3) ^c	48.2	(317.7)	(431.8)
United Airlines	95.8	(494.1)	(956.8)	(1,355.1)
USAir	(427.2)	(284)	(1,223.4)	(1,934.6)
Total	(1,103.7)	(1,785.3)	(4,413.3)	(7,302.3)

^aOperating loss.

^bFor the six months ending December 31, 1990.

^cOperating loss.

the airlines generally lost at least several hundred million dollars each year and sometimes much more than that [11,12]. The seven airlines combined for a loss of more than \$7 billion during these three years.

Revenue management, a name far more industry neutral, began to gain favor. References to revenue enhancement and revenue management replacing yield management can be found as early as 1990 and began to proliferate thereafter [13–14].

For many, the desire to “rebrand” yield management dovetailed nicely with the desire to broaden its scope to include a wider array of reservation inventory controls than used by airlines, explicit recognition of variable costs, and price optimization (that is, the determination of the best prices to offer). For example, cruise ships might offer 8–12 cabin categories; cruise line yield management inventory controls explicitly considered the financial impacts of alternative upgrading (and upselling) policies when taking reservations, such as allowing some customers to make a reservation for a less expensive cabin category but guaranteeing them accommodation in a more expensive cabin category. Yield management also led cruise lines to reevaluate and modify the price differentials between cabin categories, as supply and demand imbalances at the cabin category level were analyzed with greater precision. The wider array of variable costs associated with hotel stays led hotel yield management efforts to consider profit, rather than revenue. Yield management thus expanded to include practices beyond those adopted by airlines.

By 1993, *revenue management* was well on its way to replacing *yield management*. Presentations at multiindustry conferences on this topic included sessions in which speakers differentiated revenue management from yield management. Perhaps as testament to the strength of this conversion, the annual International Air Transport Association (IATA) Conference on Yield Management, initiated in 1988, was rebranded as the IATA Conference on Revenue Management in 1993; in 2001 it experienced further rebranding, becoming the IATA Revenue Management and Pricing Conference. There now seems to be growing

support for relabeling revenue management as revenue and pricing optimization (RPO).

Firms in virtually every segment of the travel industry now possess revenue management programs. And each year, these programs improve. But let us not get ahead of ourselves. Every story has its beginning and this is certainly true of revenue management. To tell it, we begin with the airline industry.

YIELD MANAGEMENT BEGINS

The total number of reservations that can be accepted for a flight is generally greater than the number of seats on a plane. It is known as the *overbooking level*, although there was a time, probably short-lived, when airline staff preferred the term “revenue coordination” due to the negative connotations of overbooking [15]. Airlines generally overbook a flight in anticipation of reservations being cancelled, passengers with reservations who fail to show up for their flights (no-shows), and other reasons. While overbooking has been a standard airline practice for over 50 years, the science of overbooking took a dramatic step forward in the mid-1960s. In that respect, this might well mark the beginning of yield management in the travel industry.⁵

As noted by Rothstein, “[w]hen our American Airlines O[perations] R[esearch] Group initiated its research in 1964, the scant literature on overbooking yielded no models or methods that had been implemented.” A year or two later, however, a newly developed overbooking program was implemented at American, dramatically improving the airline’s ability to forecast oversales (customers with tickets that show up for a flight but for whom no seats are available) and set overbooking levels that allowed the airline to achieve higher load factors on high demand flights, without increasing the number of passengers who were denied boarding [15].

While working in the airline industry in the 1980s, it was the author’s experience that

⁵Our decision to use the developments in the 1960s as the starting point for yield management reflects our emphasis on the science, not simply the practice, of the discipline.

the overbooking models used by some airlines remained relatively rudimentary while those of others had evolved considerably since the 1960s. At American Airlines, the overbooking model developed by Rothstein and his colleagues in the operations research group was replaced in 1976 by one which recognized the revenues and costs associated with overbooking levels and attempted to maximize profitability. This model was further enhanced in 1987 [4].

The science of overbooking involves as many as five forecasts:

1. the probability of reservation cancellations prior to departure;
2. the probability of passengers with reservations failing to show up for their flight;
3. incremental demand when cancellations occur before departure;
4. the cost of oversales (this may not be linear for a flight and also, it varies based on a variety of flight characteristics and the ability of the airline to retain the passenger on a different flight that it operates);
5. the incremental revenue obtained from additional reservations.

For operational reasons, it may be desirable to limit the number of oversales on a flight to a value less than what would be financially optimal. Such constraints have been incorporated into overbooking models.

Forecasting incremental demand (additional demand up to a flight's departure) allows implementing better overbooking levels prior to a flight's departure. The overbooking levels for an optimally managed flight will generally decrease over time; that is, as the number of days before a flight's departure decreases, so too will its overbooking level. The more likely it is that incremental demand will back-fill cancellations, the lower the levels of pre-departure overbooking. If all goes well, the number of reservations holding at departure will be equal to the desired departure-time booking level.

The financial benefits of overbooking were substantial for airlines, as it probably

allowed some of them to increase their load factors on high demand flights by as much as 10 percentage points (e.g., from 85%–95%), and possibly more. An airline with 750 flights per day, an average fare of \$175 per passenger per flight, average flight capacity of 120 seats and an annual load factor of 61% would have annual revenues of approximately \$3.5 billion. If 10–15% of its flights sold out, selling just one additional seat on these flights increases annual revenue by approximately \$4.8–7.2 million. Increasing the load factor of these flights by 10 percentage points could mean an annual increase of \$57–86 million. Putting this into context, in 1981 and 1982, on passenger revenues of approximately \$3.4 billion, American Airlines had operating income of \$44 million in 1981 and lost \$18 million in 1982 [16]. To say that an airline's revenue management capabilities, in terms of the accuracy of its overbooking levels could be the difference between an annual loss or profit, is not much of a stretch.

While the substantial financial benefits to the airlines from overbooking are clear, less visible is the consumer benefit, which can also be substantial. When done well, overbooking allows more consumers the ability to purchase and use their product of choice. When advance notice is given that a flight, hotel, or other service is sold out, but actualized demand turns out to be less than capacity, some consumers will have been deprived of their ability to use that service and will have had to choose something less desirable. They will have been inconvenienced unnecessarily.

Without a doubt, airline overbooking would not yield nearly the benefits it does had the airlines not adopted a business process they initially heavily resisted. On heavily booked flights, it is relatively common for passengers to inquire whether volunteers are needed to give up their seat on the flight in exchange for some form of compensation and a seat on a later flight. Many show clear disappointment when the airline's Gate Agent responds that all passengers with reservations can be accommodated on the flight and no such volunteers are needed.

This was not always the case. Prior to 1978, not only did airlines not seek volunteers, airline executives did not believe that

asking for volunteers would work when more passengers with reservations showed up for a flight than there were seats on the plane. Each airline developed its own rules and procedures for determining who would fly and who would not.

In 1966 and 1967, Professor Julian Simon contacted airlines with an idea for how they could obtain volunteers in exchange for an agreed upon level of compensation. None of the airlines thought much of his proposal, some even being derisive in their replies to him. Rather than let the concept die, he persisted in his efforts to obtain support for it [17]. More than 10 years later, his ideas finally took hold when economist Alfred Kahn became head of the Civil Aeronautics Board. The CAB mandated that airlines adopt a plan for obtaining voluntary oversales [18].

Airlines varied in the types of compensation they offered, some giving travel vouchers for use on future trips while others gave free tickets for a future flight.⁶ The success of each program varied, but overall, the volunteer program enabled airlines to try more aggressively to fill each seat. Between 1978 and 1991, the number of involuntary oversales fell from 6.4 per 10,000 passengers boarded to 1.1 per 10,000, while the number of voluntary oversales during that same period increased from approximately 1 to 15 per 10,000 passengers boarded. As you might imagine, the frequency with which passengers complained about being denied boarding also dropped dramatically [18].

Although the practice of overbooking in the airlines certainly continues, the introduction and proliferation of nonrefundable fares has significantly decreased its benefits. The need for overbooking has also declined as cancellation and no-show rates have declined dramatically.

⁶Offering a credit for future travel may increase an airline's revenue as it can stimulate trips that would not have been taken and the cost of the trip may be for more than the voucher. Compensating passengers with a free trip does not allow for this. Travel credits are now more typical.

YIELD MANAGEMENT EXPANDS

Prior to the mid-1970s, airline fares were highly regulated. Restriction-based discounted fares, so familiar today, were not available. The discounted fares that were available tended to be oriented to specific groups such as children, stand-by passengers, senior citizens, and other class-based categories. The availabilities of these fares were based solely on eligibility.

When the US airline industry was deregulated in 1978, the proponents and the detractors of deregulation envisioned major industry changes. It is safe to say, however, that of the changes that were made possible by deregulation, the fare-related impacts of revenue management were far from anyone's expectations.

In 1977, just prior to deregulation, American Airlines introduced discounted fares known as Super Savers on transcontinental flights and then throughout their system in 1978. These fares were developed in response to an alarming development that began during the summer of 1976. Businesses had sprung up that organized group charters, buying large blocks of seats from airlines at significant discounts and then re-selling them for prices that were lower than the regular fare. Discussing the situation with his staff, Bob Crandall, who was to become president of American Airlines, but was then head of marketing, said, "We're already selling 40 percent of our seats at regular fares, so why can't we figure out a way to sell the other 60 percent at a fare cheaper than what a charter operator can get?" [19].

Super Savers were American's response and other airlines followed American's lead. Super Savers required advance purchase and had a 14-day minimum-stay requirement (a round-trip purchase was thus required). Recognizing that business travelers were willing and able to pay higher fares, the restrictions were designed to prevent business travelers from purchasing them. In addition, on many flights the number of Super Saver tickets that could be purchased was controlled (i.e., only a limited number of sales were permitted) to avoid displacing demand from later-booking business travelers who were willing to pay

higher fares. For the most part, the airlines relied on various “rules-of-thumb” and the judgment and intuition of inventory control staff to set and manage discount allocations. Revenue management was expanding from overbooking to *discount allocation* control, although controlling the number of discount fares sold so as to maximize flight revenue was not carried out with the accuracy or mathematical support that was soon to come.

Nonetheless, the introduction of Super Savers was truly a watershed event in the history of revenue management. It was a unique concept. Not only did it allow the same product to be offered for sale *at multiple prices simultaneously*, but consumers of the products, not the firms that were offering them, were empowered to trade-off purchase and usage restrictions versus price and decide which product to purchase. The number of Super Savers that could be sold on any flight, however, was up to the discretion of the airline.

At this point, it is useful to examine two key points in more detail:

1. Large financial benefits are possible when a seemingly homogeneous product is sold for multiple prices.
2. The extent to which these gains are achieved depends on how well these sales are controlled.

Suppose a flight has a seating capacity of 120, the full fare is \$380 and the discounted fare is \$210, a 45% discount from full fare. As shown in Table 2, if offering discounted fares leads to incremental passengers without reducing the number of full fare passengers, the incremental revenues can be significant. If, in addition to selling 70 full fare tickets, 20 discounted fares can be sold, the flight's revenue increases by

more than 15%. But if some of these discounted fares are sold to those who would have purchased a full fare, the gains are quickly eroded. Even worse, *revenue may decline*. If 5 of the 20 discounted fare tickets are purchased by passengers who would have purchased a full fare ticket, the incremental revenue is only 8.6%. If the discounted fares are sold to 12 of these passengers, revenue actually declines by more than one percent, although the flight's load factor, the percentage of seats occupied, increases by more than 11%. Had the discounted fare been \$125, a 67% reduction, revenue declines when only 5 of the 20 discounted fares are sold to those who would have purchased a full fare. As we shall discuss, this was soon to be a real scenario. Profit levels erode even faster when the variable costs of transporting and servicing passengers are included.

The potential value of optimally managing discount fare sales may be appreciated more easily by analyzing the potential impacts of “small mistakes.” In the example above, the incremental revenue drops by approximately 9% for each passenger that purchases a discounted fare rather than the full fare (i.e., a flight with 69 full fare passengers and 20 discounted fare passengers earns 9% less revenue than a flight with 70 full fare passengers and 20 discounted fare passengers). Taken from that perspective, the financial impact of one less full fare sale on a flight, let alone several, is sufficiently great as to merit careful management.

Now, consider those flights for which demand is sufficiently high to fill every seat. Further, suppose that none of the passengers willing to pay full fare purchases a discount fare. What is the financial impact of displacing a potential full fare passenger by a passenger purchasing a discounted fare? That is, how much less incremental revenue

Table 2. Potential Revenue Impacts of Offering Two Fares

Full Fare Passengers	Discounted Fare Passengers	Load Factor (%)	Revenue (\$)	Change in Revenue (%)
70	0	58.3	26,600	N.A.
70	20	75.0	30,800	15.8
65	20	70.8	28,900	8.6
58	20	65.0	26,240	-1.4

Table 3. Potential Revenue Impact of Displacing Full Fare Passengers

Full Fare Passengers	Discounted Fare Passengers	Load Factor (%)	Revenue (\$)	Incremental Revenue (\$)	Revenue Reduction (%)
70	0	58	26,600	Baseline	N.A.
70	50	100	37,100	10,500	Baseline
69	51	100	36,930	10,330	1.6
65	55	100	36,250	9,650	8.1

is earned if there are 69 full fare passengers and 51 discount fare passengers on the flight, rather than 70 full fare passengers and 50 discount fare passengers?

As shown in Table 3, the flight's incremental revenue decreases by approximately 1.6% for each full fare passenger that is displaced by a discount fare passenger. Perhaps, this does not seem like much. After all, is not 98.4% of perfect still pretty good? Is it really worth the effort to pursue an extra 1.6%? If this airline has 1000 flights per day and 15% of its flights sell out, this "allocation error" results in \$9.3 million less revenue than the airline could have earned. Allocation errors of only several seats per flight on sold out flights lowers its annual revenues by tens of millions of dollars. And while these numbers are only illustrative, they are sufficiently accurate to demonstrate that the financial difference between optimally managing discount allocations and only managing them well is extraordinary. This is why travel companies have been willing to invest heavily in achieving marginal improvements in their revenue management programs. It was a lesson that was quickly learned and acted upon by some, but not all, airlines in the early 1980s.

Although Super Savers provided the needed innovation in the pricing structure, a few more years and an impending financial crisis would be required before the airlines fully recognized and embraced the practice of offering multiple prices with a variety of purchase restrictions to obtain incremental sales and profits. Indeed, it was not just the pricing structure, but also the ability to expertly manage the discount allocations that was also needed; but this was not yet in place.

Fortunately, the work to do this had already begun. Although not aware of how important it would ultimately be, in 1972 the Operational Research Branch of British

Overseas Airways Corporation (BOAC) laid out the underlying theory and insights for using operations research techniques to set discount control allocations to maximize flight revenue when multiple fares are sold. The ideas were presented by Kenneth Littlewood, a member of the team, at a meeting of the Airline Group of the International Federation of Operations Research Societies (AGIFORS). At the end of a paper that was written primarily to document BOAC's efforts to implement mathematical and statistical methods to set overbooking levels to maximize revenue, Littlewood also described a method for using demand forecasts and optimality conditions to set limits on the number of discounted fares that should be sold for a flight to maximize flight revenues. According to Littlewood, the ideas on discount allocation were "still in its infancy," but the introduction of new low fares by Skytrain for regular London–New York service highlighted the need to control the allocation of low yield fares [20,21]⁷. He could not have envisioned that this method, eventually termed *Littlewood's Rule*, was to become the basis for discount allocation algorithms employed in revenue management systems at many airlines.

Littlewood's key observation (somewhat simplified here) was that to maximize a flight's revenue when two fares are offered (e.g., let Y be the full fare and D the discount fare), the discounted fares should be sold so

⁷The paper was entitled "Forecasting and control of passenger bookings" and was published in the AGIFORS 12th Annual Symposium Proceedings, October 1972, pp. 95–117. Fortunately, this ground-breaking and quite readable paper has been reprinted and the reference listed at the end of this article is far easier to access.

long as

$$D \geq P \times Y \text{ or, equivalently, } P \leq D/Y$$

where P is the probability that selling an additional discounted fare will result in one less full fare ticket sale.

This implies that discounted fares should be sold so long as the ratio between the discount fare and the full fare (D/Y) is at least as great as the likelihood that the overbooking limit will be reached if no more discounted fares are sold. Essentially, it is a comparison between the revenue received from a discounted ticket and the expected marginal revenue resulting from not selling the discounted fare in anticipation of selling a full fare in its place. It is interesting to observe that the decision as to whether or not to accept an additional reservation for a discount fare does not depend on the demand distribution for discount fares, but it does depend on the demand distribution for full fares.

In 1980, Bill Swan, a member of the American Airlines Operations Research Department, modified and extended Littlewood's methodology for implementation at American Airlines. Such a system was implemented in 1982 [4]. American was probably the first US airline to implement such an advanced method for determining discount allocations. This method was extended to multiple fare classes and has come to be known as the expected marginal seat revenue (EMSR) approach. The earliest published work on this method, including extensions and modifications of the approach can be found in Refs 22–25.

Discount allocation controls were designed to work within airline reservation system control structures. The mechanisms by which reservation systems controlled fare availability differed from that of many other industries. Each fare would be mapped into one of perhaps five or eight fare classes for a flight, depending on the reservation system. Fare classes were designated by letter codes. For example, F, C, and Y were commonly used for first class, business class, and full coach fares, respectively. Discounted coach fare classes included letter codes M, B, V, H, and Q. When

a fare class was available, all fares that were mapped into it could be sold.⁸ When a fare class was closed, none of the fares mapped into that fare class could be sold. Typically, many fares were assigned to each fare class [4,22]. Over time, the number of fare classes has increased considerably. A flight may now have as many as 16 different fare classes.

Consequently, yield management assumed an indirect responsibility for price setting. While others determined the actual fares that *could* be offered to the public, yield management controlled when and which fares were *actually* offered by determining when fare classes were open for sale and when they were closed. Fare classes opened and closed multiple times during the booking period reflecting bookings, cancellations, and revisions to discount allocation decisions based on changes in incremental demand forecasts.

As you might imagine, demand forecasts play a critical role in setting inventory allocations. Demand was forecast at the fare class level. Time series models, such as exponential smoothing and booking profiles that provided estimates of how many reservations were typically received during various time periods prior to departure, were commonly relied upon to forecast demand by fare class. Consequently, the forecasts of future or incremental demand were independent of potential yield management or pricing actions (except to the extent that analysts implemented manual overrides). Even with such simplifications, the forecast models performed well.

With a pricing structure in place that allowed airlines to target fares at multiple market segments and the ability to control the availability of these fares based on science rather than human intuition and judgment, the airline industry, or perhaps more specifically American Airlines, was prepared to

⁸In some cases, fare-specific restrictions prevented a fare from being sold when its fare class was available. For example, if a fare with a 21-day advance purchase restriction was one of the fares that was mapped into the V fare class, that fare could not be sold 18 days prior to the flight, even if the V fare class was still open.

demonstrate that revenue management could transform the competitive landscape in ways that no one had previously imagined. All that was needed was the catalyst for action.

That catalyst came in the form of People Express, a low-cost airline that had begun operations in 1981 by offering low-fare short-haul service between cities that had limited air service. For \$23, you could fly from Newark, New Jersey to Buffalo, New York; for \$35 you could fly from Newark to Norfolk; these fares were 50–80% lower than those offered by other carriers. Over time, however, People Express expanded its route structure and by 1984 was competing on the same routes that were flown by major carriers such as American Airlines. Faced with such competition, the major carriers faced a dilemma: matching the fares offered by People Express would enable them to keep their customer base but not allow them to cover their costs, whereas not matching the low fares would result in the loss of too many passengers [26].

American's competitive response came in January 1985, in the form of its Ultimate Super Savers, restricted fares that were discounted as much as 70% so as to be competitive with those of People Express. The fares provided far greater discounts than Super Savers. Also, new restrictions such as limited refundability levels were included. Although discount allocation controls in the reservation system were now automated and benefited from data feeds from decision support systems, American's initial ability to optimally manage the discount allocation levels left much to be desired simply because its historical passenger demand data did not reflect the level of demand for the new fares. With each passing month, however, American's ability to maximize its revenues by controlling and managing the availability of these fares would improve. Other airlines would also ramp up their investments in methods and systems to better control discount fare availability. The stage was set for the introduction of a wide variety of discounted, restricted fares whose availability would seem to appear and disappear as if by magic and for no valid reason. With that, the

discipline known as yield management would soon enter the public lexicon.

The business community did not yet understand the potential benefits of the new pricing structure. As reported by Time, "To Wall Street, American's move looked like an attempt to get out in front of the competition by jumping off a cliff. Many airlines are already losing money, and discount fares may mean bigger losses. Stock prices of all the large airlines that joined in last week's fare war fell sharply" [27]. In fact, however, American enjoyed great financial success during the next few years; revenue management was only one of the reasons for this, but it was an important factor.

Although it had a more gradual impact on revenue management, the Airline Deregulation Act of 1978 also transformed airline routes. Given much greater flexibility in determining their routes and schedules, major airlines developed the hub-and-spoke system in the 1980s. Major airlines reduced their frequency of nonstop service between small and mid-sized cities (sometimes dropping these routes), forcing more passengers to take connecting flights. For example, whereas about 10% of American's passengers took connecting flights in 1980, by the mid-1980s about two-thirds of the passengers going into a hub airport were connecting to another flight [4]. By the late 1980s, airlines began to make fare allocation decisions that reflected passenger itineraries: this aspect of revenue management is known as *traffic management*.

For airlines that experienced significant increases in their volume of connecting passengers, the traffic management aspect of revenue management was significant. When most passengers fly point-to-point, airlines that attempt to maximize their revenues/profits by setting discount allocation levels on a flight-by-flight basis perform rather well. As connecting traffic increases, however, this practice becomes more problematic. Indeed, as we shall soon see, in some industries such network-related issues can dominate revenue management decisions. Traffic management, that is the practice of setting allocation levels (and not necessarily only discounted fare allocations)

that reflect the incremental value of a passenger's revenue to the airline's flight network, became increasingly important and eventually became incorporated into airline revenue management systems.

The importance of traffic management can be seen in the following example. Consider a person wanting to fly from Austin, Texas to London, England on a discounted fare of \$329. As there is no nonstop service from Austin to London, this passenger might fly from Austin, Texas to Dallas/Forth Worth, and then from Dallas/Fort Worth to London. Suppose someone else wants to fly from Austin to Dallas/Fort Worth (DFW) on the same flight and is willing to pay the Austin to DFW full fare of \$189. Further, suppose there is only one seat still available for sale on the flight from Austin to DFW. Which reservation should the airline accept if it wants to maximize its revenues?

Excluding variable costs and the likelihood of either passenger booking a different flight on the same airline, the answer is, it depends.⁹ Specifically, if the flight from DFW to London becomes full and demand must be turned away, it is highly likely that the airline earns greater revenue by transporting the passenger flying from Austin to DFW and turning down the passenger flying from Austin to London. If, however, the flight from DFW to London departs with empty seats, the airline is likely to earn greater revenues by transporting the passenger flying from Austin to London.

Compared to overbooking and discount allocations, traffic management is significantly more difficult to address and generates more modest incremental revenue (although certainly significant) than setting flight-independent discount allocation levels. Although the benefit of overbooking has declined in recent years as nonrefundable fares have become more prevalent, in the

1980s and 1990s, approximately 40–50% of the potential benefits of revenue management could be attributed to overbooking, 30–40% to discount allocation, and 10–20% to traffic management.¹⁰ While 10% of a \$500 million annual benefit is certainly significant, it made sense for many airlines to initially focus on overbooking and discount fare allocation, the more valuable areas, prior to traffic management. For other industries, however, this was not the case.

FROM YM TO RM: BEYOND THE AIRLINE INDUSTRY

As revenue management spread to the hotel industry and then elsewhere, its focus remained on inventory control. Prices continued to be set independently of revenue management. Marriott began investing in revenue management as early as 1985 [28] and other hotel companies soon followed. According to Sheraton's Director of Marketing Geoff Ballotti, Sheraton began implementing a hotel revenue management system offered by Control Data Corporation (CDC) in 1987, implementing the system at 28 of its hotels [5–7]. Hilton also implemented a revenue management system in the late 1980s.

Some hotel chains began to experiment with offering discount rates with restrictions such as advance purchase requirements, but for the most part, it would take several more years until hotels integrated advance purchase requirements and refundability restrictions into their pricing structures. Rather, discounted rates were targeted to specific dates (e.g., weekends, holidays) or groups (e.g., children, travel agents, senior citizens) or were unrestricted rates off the full rate. The discounted rates were tied to the full rate (known as the rack rate) by some pre-determined percentage or value. Consequently, the early hotel revenue management systems served a slightly different function than airline systems, as they were used to

⁹Such factors should, and are likely to, be considered in an airline's revenue management system although it was more likely than not for such factors to be ignored or only marginally considered in the initial revenue management systems implemented by the airlines.

¹⁰Personal communication with Barry Smith, former Chief Science Officer for SABRE and also the author's experience.

control which of several rate tiers should be offered, rather than controlling discount allocations. Each rate tier included a set of rates.

The revenue management systems measured demand pressure for each check-in date using four primary criteria: reservations on the books, time until check-in date, a forecast of incremental demand for that date, and a forecast of remaining rooms. As the magnitude of the demand pressure increased, these systems would recommend raising the rate tier offered. Consequently, many of the various rates offered by the hotel to the general public would increase, or decrease, simultaneously, by pre-determined amounts. Some discounted rates would not be included in a rate tier, so these rates would not be available when that rate tier was offered.

The initial application of revenue management in the hotel industry suffered from missteps that concerned some hotel executives sufficiently to delay their adoption of revenue management systems. Borrowing from the airline industry's revenue management "playbook," perhaps a little too much, some of the initial hotel revenue management systems incorporated a design simplification that served the airlines well; they essentially ignored traffic management, the network aspect of revenue management.¹¹ Revenue managing a flight independently of others is similar to revenue managing arrival dates at a hotel independently of other dates. Unfortunately, this simplification was apt to yield poor rate recommendations during peak periods for hotels with a high proportion of multiple night stays. When guest stays span multiple dates, managing dates independently is apt to lead to pricing mistakes.

As it turns out, compared to increasing rates on dates that ultimately sell out, hotels generally earn far greater revenues and profits by limiting the number of shorter stays so that they can accept a greater number of longer stays that span these nights. This is

typically referred to as optimizing by *length-of-stay* (length-of-rent in the car rental industry). It is far more profitable to earn \$149 per night for four nights than \$229 for a one-night stay. Recommendations to close the lower rate tiers for a peak night to all guests, regardless of whether they wanted to stay for one, four or seven nights, could easily discourage those guests who wanted to stay several nights or longer. Unfortunately, the early hotel revenue management systems were not designed to analyze demand patterns across dates and address this issue. Nor were many hotel reservation systems designed with the controls needed to implement such decisions. The systems were not designed to control room inventory in ways that would stimulate or accept demand from guests wanting longer-stays, while simultaneously limiting the number of shorter-stays on peak nights.

A simplified example illustrates this trade-off. Consider a hotel with a rate of \$149/night, for which there is sufficient demand to sell-out on Wednesday night, even if the rate increases to \$229/night. As shown in Table 4, increasing the rate from \$149 to \$229 on Wednesday, an increase of more than 50%, results in 1135 occupied rooms during the week and the weekly revenue exceeds \$193,000. Further, every room is occupied on Wednesday night.

Conversely, if the hotel implements length of stay (LOS) controls so that more of the reservations it accepts that span Wednesday night include the surrounding days, and does not increase its average rate on Wednesday, the number of rooms occupied during the week increases by 195. The weekly revenue for the hotel increases to \$198,000, about a 2.6% revenue increase. In this scenario, not all of the hotel rooms are occupied on Wednesday night, reflecting the uncertainty associated with holding back rooms for longer stay reservation requests. In actual implementation of length of stay controls, some hotels have claimed revenue increases of 8–10% or even more when compared to increasing rates on peak nights [29]. Indeed, in the above example, if the Wednesday rate had only increased to \$189, an increase of approximately 25%, the hotel would earn

¹¹Nor were overbooking recommendations incorporated into these systems, although this was more likely for business process reasons. Hotel executives tend to be very cautious about systematically overbooking.

Table 4. Comparison of Impacts from LOS Controls versus Increasing Price

	Mon	Tue	Wed	Th	Fri	Total
Available rooms	300	300	300	300	300	1500
Occupied rooms if Wednesday rate increases to \$229	190	235	300	220	190	1135
Revenue if Wednesday rate increases to \$229 (\$000)	28.3	35.0	68.7	32.8	28.3	193.1
Occupied rooms with LOS controls and rate of \$149	245	280	295	275	235	1330
Revenue with LOS controls and rate of \$149 (\$000)	36.5	41.7	44.0	41.0	35.0	198.2

9.4% more revenue by using length-of-stay controls rather than increasing its rate.

In practice, combining a rate increase for shorter stays while allowing longer guest stays to access lower rates is generally the most profitable pricing strategy for hotels during peak periods. The benefits of this strategy are recognized within the hotel industry. Hotel systems and practices have been redesigned to enable this strategy to be effectively implemented: no longer can guests make a reservation for a longer stay to obtain a lower rate and then cancel some of the days in the reservation or simply check-out early.

Aggressively increasing rate tiers on peak nights also had a negative unintended side effect. Able to provide hotels with high volumes of demand over the year, many corporations negotiated fixed rates with hotels that were significantly lower than the unrestricted rates. The corporate negotiated rates were not affected by the hotel's pricing actions. Raising the hotel's rates on peak nights might reduce hotel profitability as it could result in accepting more guests with lower corporate rates; because the rate increase slowed down the pace of bookings for publically available rates, it enabled corporations with the lower negotiated rates to access more rooms on peak nights, which was exactly the opposite of what the hotels wanted.

By 1990 these shortcomings were recognized and soon thereafter, addressed. Marriott's first generation yield management system with length-of-stay optimization was implemented in 1991. Prior to this, Marriott's yield management systems had gone through two generations. A test of the system at the Munich Marriott during a high demand

week helped the hotel obtain a 12.3% year-over-year revenue increase, despite an 11.7% reduction in average daily rate [5–7].

The adoption of yield management by the hotel industry in the late 1980s and early 1990s is well documented. Less information is available about the passenger railroad and cruise line initiatives at this time. Given permission to provide consulting and system development expertise to other firms, the American Airlines Operations Research Group began developing a yield management system for Amtrak in 1987 and a year later was doing the same for Royal Caribbean Cruises Ltd. (RCCL). Focused on enhancing the inventory control capabilities of these firms, these systems did not provide any pricing recommendations.

Among the first areas to be addressed by the RCCL effort was improving the accuracy of pre-departure cancellation rate estimates for individual and group reservations [30]. At the time, cruise lines typically estimated cancellation rates based on fixed projection rates that reflected how much money had been received by the cruise line and possibly one or two other factors. Known as a handicapping formula, the methods generally provided reasonable average estimates over the course of the year, but were subject to "catastrophic" breakdowns on individual sailings, leading to undesirable pricing actions. Over-forecasting cancellations could lead to selling cabins at highly discounted rates close to departure date. Under-forecasting cancellations could require upgrading passengers into much more expensive cabins, or even worse, fully or partially refunding their purchases while also moving them to other departures. Segmenting reservations based on a variety

of attributes (e.g., travel agency, itinerary, and type of group), and containing updating mechanisms to capture trend and seasonality, the new method provided more accurate cancellation rate estimates [31]. Having more accurate estimates of the number of additional cabins that needed to be sold on a departure enabled RCCL to make more profitable pricing decisions for each cruise.

Other elements of the RCCL yield management initiative included a group evaluator model and a variety of forward-looking reports directing analyst attention to those departures most in need of oversight and action. While the scope of RCCL's initial yield management system might be considered rather modest, it was a key factor in enabling RCCL to better manage and price its inventory, including implementing a variety of pricing innovations. In 1992, Brian Rice, then RCCL's director of revenue planning and analysis, and now CFO, conservatively estimated the incremental revenue from these efforts at over \$20 million/year, or about 2–3% of RCCL's annual revenue [5–7].

Approximately two years after Amtrak had initiated its revenue management effort, SNCF, the French national railway, did the same [32,33]. By 1989, revenue management efforts were also initiated at Avis, a rental car company. By the early 1990s all of the major car rental firms had implemented revenue management systems or were preparing to do so. The ability to evaluate and control reservations based on length-of-rent was included in all the first generation car rental revenue management systems. The revenue management system implemented at Hertz also included fleet planning and fleet deployment capabilities enabling Hertz to better determine where and when it was financially advantageous to transfer cars between rental car locations due to projected supply and demand imbalances [34]. Doing so probably made Hertz the first company to integrate revenue management with operational decisionmaking.

Revenue management continued to spread to other segments of the travel industry, including tour operators, time-share exchange, theme parks, and even yacht rentals as well as industries other

than travel. Within a few years, additional revenue enhancement techniques were included in revenue management initiatives. Perhaps the most critical development was the inclusion of price optimization capabilities; no longer would revenue management simply control the availability of previously set prices. Instead, revenue management efforts would include determining the best price levels. In some cases, dynamically re-pricing a product to maximize profits based on current and forecast supply and demand extended the underlying mathematical models to include demand elasticity estimates: forecasts of how demand would change in response to offering alternative prices. Some (i.e., published) accounts of revenue management systems that incorporated dynamic pricing capabilities include National Car Rental [35], The Moorings [36], and Princess Cruises [37].

The revenue management initiative for Princess Cruises, begun in 1997, was implemented in 2000. While the system included typical inventory controls, it also included a pricing analytics engine providing insights on the extent to which promotional prices were needed to stimulate sales on a departure. Of all the capabilities of the revenue management system, Princess staff believed this capability to be the most beneficial.¹²

Price optimization continues to be of great interest to many travel industry firms. Only a relatively few, however, have invested significant resources. At least for some of these firms, however, the returns have been extraordinary, easily eclipsing the 4% to 7% returns typically ascribed to the inventory allocation controls of revenue management. Anecdotally, price optimization capabilities appear to be capable of generating revenue increases of 10–15%.¹³

For many years, pricing has been treated as mostly art and very little science. For the most part, the science of pricing focused on

¹²Personal communication with Princess Cruises staff.

¹³These estimates reflect the author's experience as well as personal communication with Barry Smith.

estimating the costs of production and building in a reasonable profit margin. The product's price was simply the result. While many firms continue to engage in that practice, it occurs less often as the principles of revenue management obtain a greater foothold. The systematic integration of supply and demand forecasting with product design and market segmentation concepts has proven successful, although there have certainly been instances of failure and setbacks along the way. As was the case when revenue management was initially applied to the hotel industry, many of these failed efforts resulted when techniques that proved successful in one industry were used in another, without sufficient regard for the differences in the way business was conducted.

Over the past 20 years, the financial benefits of value-based pricing have become more widely accepted and communicated. The science of revenue management provides a powerful mechanism that enables value-based pricing to succeed. Indeed, with restriction-free pricing becoming more and more prevalent in the airline industry, the traditional discount allocation controls of revenue management are now giving way to an increasingly strong focus on maximizing revenue via dynamic pricing to achieve pricing optimality.

At the heart of any dynamic pricing optimization system is forecasting demand at alternative prices and then estimating the prices that will maximize profit. From a practical perspective, forecasting demand at different prices can be both complex as well as data intensive, as demand is affected by a number of factors other than price. While many companies have attempted to incorporate such variables into regression-based forecasts, such efforts often produce less than satisfactory results. Data sparsity and the inability to model many key relationships among the variables are some of the reasons that price-demand relationships are less robust or accurate than desired. Manual overrides and factors designed to prevent forecasts and recommendations from being too extreme are often integral to such systems. While some of these methods have proven useful, others have produced

sufficiently unreliable recommendations that firms stopped using the systems.

More recently, however, alternative modeling approaches such as disjunctive mapping are being developed to address these issues [38,39]. The widespread use of robotic pricing tools that capture competitor prices enables price-sensitive demand forecasts to explicitly reflect different competitive situations and support what-if analyses, as historical data has become available to estimate the likelihood of alternative competitor reactions. Indeed, one of the challenges of price-elasticity modeling is that in practice, demand curves may not be static; they depend on the directional shift of price and possibly other factors. For example, when price increases from A to B , the magnitude of the change in demand level may not be equivalent to the magnitude of the change in demand when price decreases from B to A . Such modeling and estimation complexities are more easily addressed when competitor prices are retained. Given the potential benefits of dynamic pricing, and the recent availability of data to support demand forecast modeling, we anticipate that dynamic pricing will be a strong focus of travel companies during the next decade or two.

CONCLUSION

Written for academics and experienced practitioners of revenue management as a "single-source reference for the major theory and application issues," a comprehensive treatment of revenue management was published in 2004 by Kalyan Talluri and Garrett Van Ryzin. The book is intended for those who have advanced degrees in mathematically-oriented disciplines such as operations research, statistics, or economics, although portions of the book are accessible to those without such skills and are interested in obtaining a more detailed understanding of the theory underlying revenue management [40].

From a relatively obscure business practice only 50 years ago, revenue management has come a long way. Dominated by practitioners until 1990 and perhaps longer,

the number of academic researchers may now surpass the number of practitioners. Indeed, the subject now boasts two dedicated journals: *The Journal of Revenue and Pricing Management* was initiated in 2002 and was joined by the *International Journal of Revenue Management* in 2007. In addition, articles on revenue management appear in a wide variety of journals and books.

Will the term revenue management be retained? Will it be replaced by pricing and revenue optimization or something else? What is your forecast?

Acknowledgments

I greatly appreciate the time given to me by both Kenneth Littlewood and Barry Smith to discuss some of the ideas in this article. They were able to provide me with key pieces of information that filled in gaps in the historical record and allowed me to better understand the motivation behind industry developments. As my mentor in revenue management at American Airlines, I am deeply indebted to Barry for both, the time he has given to me and value the friendship we have developed. I also owe a large debt of gratitude to Tom Cook, who headed the American Airlines Operations Research Department in 1984. Without his support and trust, I would never have had the opportunities in revenue management that have captivated me for more than 25 years.

Consider a seller who is endowed with a fixed number of units of a product that he/she can sell to a price-sensitive and stochastically arriving stream of consumers during a given selling season. The seller's problem is to dynamically adjust the product's price to maximize the revenues he/she can collect if no replenishment is possible during the sales horizon. This setting is quite typical of many industries including among others, airlines (selling seats on a specific flight), hotels (booking rooms on a particular night), and retailers (selling seasonal merchandise). Often, these problems are labeled as *revenue management* problems since operational decisions are driven solely by revenues; inventory and capacity costs are sunk and incurred independently of changes in prices and/or number of units sold. The assumption of a fixed capacity is by no means critical if we consider that in most of these industries capacity is flexible only in the long run. Moreover, capacity decisions and price decisions take place on different timescales. Issues regarding the type of airplanes to schedule on a particular route, or the number of rooms to build in a given hotel, or the amount of seasonal merchandise to purchase from an overseas supplier are decided long before demand is realized and price policies are implemented.

In this article, we discuss, specifically, the revenue management problem alluded to in the previous paragraph using a stylized mathematical formulation. We focus on the research that considers the case in which the seller has incomplete demand information. That is, there are some characteristics of the demand process (e.g., the arrival rate or the price elasticity) that the seller does not know with certainty. Through this discussion we aim at summarizing some of the fundamental theoretical results of the existing literature. The model is simplistic but, we believe that the methods used and the insights drawn are quite representative of more general models and various other settings related to revenue management and, more broadly, to inventory management. Our exposition is by no means exhaustive and we refer the reader to Refs 1 and 2 for a comprehensive review of the literature on dynamic pricing and revenue management, and to Ref. 3 for a detailed exposition on point processes and their optimal intensity control. We start reviewing the basic mathematical model under complete demand information.

DYNAMIC PRICING WITH COMPLETE DEMAND INFORMATION

Consider a stream of potential customers arriving according to a time-homogeneous and price-independent Poisson process with rate Λ . We refer to Λ as the *market size*. Upon arrival, a consumer buys the product with probability $\bar{F}(p)$, where p is the price of the product listed at this time. We can interpret $\bar{F}(p)$ as follows. We associate with each consumer a *reservation price* (that is, a maximum willingness to pay), which is distributed according to $F(\cdot)$ among the population of consumers (see Ref. 4 for more details), so that $\bar{F}(p) = 1 - F(p)$. We will assume that F admits a density f . The effective demand process or the sales process that results from

the above description is a nonhomogeneous Poisson process with rate $\lambda : \mathbb{R}_+ \rightarrow [0, \Lambda]$, a continuous, bounded, and decreasing function such that at each time t , $\lambda_t = \lambda(p_t) = \Lambda \bar{F}(p_t)$, where p_t is the price charged at time t . We will refer to $\lambda(\cdot)$ as the *demand function*. Let $\mathcal{A}$ be the set of *admissible* price processes $p = (p_t : t \geq 0)$, that is, processes for which the value of p_t depends exclusively on the history of sales and prices up to time t (but not on future unobserved events). We will denote by $\mathcal{F}_t$ this history up to time t .

Let $\mathcal{N} = (\mathcal{N}_t : t \geq 0)$ be a standard (rate 1) Poisson process. For any $p \in \mathcal{A}$ and demand function λ , we define the cumulative demand process $N_\lambda^p(t) := \mathcal{N}\left(\int_0^t \lambda(p_s) ds\right)$ and its corresponding cumulative revenue

$$\mathcal{R}(p; x_0; \lambda) := \int_0^T p_t \mathbb{1}(N_\lambda^p(t) < x_0) dN_\lambda^p(t),$$

where T is the length of the sales horizon,

x_0 is the seller's initial inventory and $\mathbb{1}(E)$ is the indicator function of the event E . The seller's dynamic pricing problem is given by the following (intensity control) problem

$$\sup_{p \in \mathcal{A}} \mathbb{E}[\mathcal{R}(p; x_0; \lambda)]. \quad (\text{P})$$

For $p \in \mathcal{A}$, Problem (P) can be rewritten as follows (see Chapter 2 in Ref. 3 for details).

$$\begin{aligned} \sup_{p \in \mathcal{A}} \mathbb{E} \left[\int_0^T r(p_t) dt \right] \\ \text{subject to} \quad N_\lambda^p(T) \leq x_0 \quad (\text{a.s.}), \end{aligned}$$

where $r(p) := p \lambda(p) = p \Lambda \bar{F}(p)$ is the instantaneous revenue rate. Let us define $p^* := \arg\max\{r(p)\}$, $\lambda^* := \lambda(p^*)$ and $r^* := r(p^*)$. It is worth noticing that despite the fact that p^* maximizes the instantaneous revenue rate $r(p)$ choosing $p_t = p^*$ for all t is in general suboptimal. The reason is that this choice could deplete the available

inventory too fast (before T) and the seller would be better off charging a higher price without necessarily sacrificing sales. On the other hand, if $x_0 = \infty$ then the seller can never deplete his/her inventory in finite time and $p_t = p^*$ for all $t \leq T$ is indeed an optimal policy.

A standard way to solve Problem (P) is by using dynamic programming. For this, let $J^*(x, t)$ be the seller's optimal revenue-to-go if the remaining sales horizon is $t > 0$ and the current available stock is x units. It follows that $J^*(x, t)$ satisfies the Hamilton–Jacobi–Bellman (HJB) equation (see Chapter 7 in Ref. 3 for details)

$$\begin{aligned} \frac{\partial}{\partial t} J^*(x, t) \\ = \max_{p \geq 0} \left[r(p) - \lambda(p) [J^*(x, t) - J^*(x-1, t)] \right], \end{aligned}$$

with boundary conditions $J^*(x, 0) = J^*(0, t)$ for all $x, t \geq 0$. One can show that there exists a nondecreasing function ζ such that the optimal price satisfies $p^*(x, t) = \zeta(J^*(x, t) - J^*(x-1, t))$. Similarly, we define a nonnegative and decreasing function Ψ such that the right-hand side of the HJB equation is equal to $\Psi(J^*(x, t) - J^*(x-1, t))$. From the first-order optimality condition for $p^*(x, t)$ we get that the HJB equation leads to the following set of identities.

$$\begin{aligned} \frac{\partial}{\partial t} J^*(x, t) &= \Psi(J^*(x, t) - J^*(x-1, t)) \\ &= \Lambda \frac{\bar{F}(p^*(x, t))}{h(p^*(x, t))}, \end{aligned} \quad (1)$$

where $h(p) := f(p)/\bar{F}(p)$ is the hazard function of $F(p)$. It is worth noticing that the first equality defines an algorithm to solve the seller's optimization problem.

Algorithm.

Step 0: Initialization. Set $J^*(0, t) = 0$ for all $t \in [0, T]$ and $n = 1$.

Step 1: Iteration. Given $J^*(n-1, t)$ for all $t \in [0, T]$ compute $J^*(n, t)$ as the solution of the first-order ordinary differential equation.

$$\frac{\partial}{\partial t} J^*(n, t) = \Psi(J^*(n, t) - J^*(n-1, t)) \quad \text{with border condition} \quad J^*(n, 0) = 0.$$

Step 2: If $n = x$ then stop. Otherwise, set $n = n + 1$ and go to Step 1.

Closed-form solutions for $J^*(x, t)$ are not generally available. A notable exception is the case in which the reservation price is exponentially distributed, $\bar{F}(p) = \exp(-p/\theta)$. In this case, it can be shown that $J^*(x, t) = \theta \ln(\sum_{n=0}^x (\lambda^* t)^n / n!)$. For the general case, Gallego and van Ryzin [5] obtain structural results for problem (P) using the HJB optimality condition.

Theorem 1 [5]. *Suppose that $r(p)$ is a concave function. The revenue-to-go, $J^*(x, T)$, is strictly increasing and strictly concave in both T and x . Furthermore, there exists an optimal price $p^*(x, T) \geq p^*$ that is strictly decreasing in x and strictly increasing in T .*

It follows that inventory and time (the seller's primary resources) have diminishing marginal returns. The following result establishes the equivalence between the market size Λ and the sales horizon T and will be useful in our discussion on how to handle uncertainty on the market size.

Theorem 2. *Let $J_\Lambda^*(x, t)$ be the seller's revenue-to-go given a market size Λ . Then, $J_\Lambda^*(x, T) = J_1^*(x, \Lambda T)$ for all $x \geq 0$ and $T \geq 0$. It follows that, under the assumptions of Theorem 1, $J_\Lambda^*(x, T)$ is an increasing and concave function of Λ .*

Proof. For any admissible pricing policy $p = (p_t : 0 \leq t \leq T)$, we define $\tilde{p} = (\tilde{p}_t : 0 \leq t \leq \Lambda T)$ such that $\tilde{p}_t = p_{t/\Lambda}$. The result follows by noticing that $\int_0^\tau \Lambda (1 - F(p_t)) dt = \int_0^{\Lambda\tau} (1 - F(\tilde{p}_t)) dt$ for all $\tau \in [0, T]$. Hence, the pricing policy p_t in $[0, \tau]$ generates (pathwise) the same revenue and depletes the same amount of inventory than the pricing policy $\tilde{p}_t$ in $[0, \Lambda\tau]$.

Another key contribution from Ref. 5 is the observation that a fixed-price policy can be asymptotically optimal as the scale of business (inventory and demand) increases. Denote by $p^D(x_0, T) := \max\{p^*, p^0\}$, where $\lambda(p^0) := x_0/T$. One can show that $p_t = p^D$ for all $t \leq T$, is an optimal policy for the deterministic version of Problem (P) (i.e., one that replaces the stochastic increments dN_t^p by its deterministic counterpart $\lambda(p_t) dt$). We let $J^{\text{FP}}(x, t)$ be the seller's expected payoff if he/she selects the price $p^D(x, t)$ for the remaining sale horizon t .

Theorem 3 [5]. *Suppose that $r(p)$ is a concave function. Then,*

$$1 - \frac{1}{2\sqrt{\min\{x, \lambda^* T\}}} \leq \frac{J^{\text{FP}}(x, T)}{J^*(x, T)} \leq 1.$$

It follows that when x and $\lambda^* T$ are both large a fixed-price policy is sufficient to achieve an almost optimal revenue. This is a very useful result that limits the seller's needs for a possibly complex dynamic pricing policy.

An important limitation of the previous result is the assumption that the seller knows the specific demand function $p \mapsto \lambda(p)$. In practice, it is rarely the case that the seller can correctly determine this function. In some cases, some incomplete information is available based on historical data. In others cases, this demand function is completely unknown (i.e., for new products or new markets). Furthermore, with incomplete demand information it is no longer true that structural properties of an optimal solution to Problem (P) will still hold. For example, with incomplete demand information there is no guarantee that a simple fixed-price policy will produce asymptotically optimal results (i.e., Theorem 3 is not guaranteed

to hold). Indeed, as the following stylized example reveals an optimal fixed-price policy can perform very poorly if the seller does not know the true demand function.

Example. Consider Problem (P) and suppose that at the beginning of the selling season the seller is uncertain about the true demand function $\lambda(p)$. He/She only knows that there is a 50% chance that $\lambda(p) = \lambda_i(p)$, where $\lambda_i(p) = \Lambda \mathbb{1}(p \leq p_i)$, $i = 1, 2$ for two fixed prices p_1 and p_2 such that $0 < p_1 < p_2 = 2p_1$. With full information, the seller knows the value of i and chooses an optimal pricing policy $p_t = p_i$ for all t with expected payoff $J_i^*(x, T) = p_i (\Lambda T - \mathbb{E}[(N(\Lambda T) - x_0)^+])$. Hence, it follows that with incomplete information the seller's payoff $V(x, t)$ is bounded by

$$\begin{aligned} V(x, t) &\leq \frac{1}{2} J_1^*(x, T) + \frac{1}{2} J_2^*(x, T) \\ &= \frac{3}{4} p_2 (\Lambda T - \mathbb{E}[(N(\Lambda T) - x_0)^+]). \end{aligned}$$

One can show that an optimal fixed-price policy (one that maximizes the seller's ex ante expected revenue) is to set $p_t = p_2$ for all $t \leq T$. The corresponding expected payoff is given by

$$V^{\text{OFP}}(x_0, T) = \frac{p_2}{2} (\Lambda T - \mathbb{E}[(N(\Lambda T) - x_0)^+]).$$

Under this optimal fixed-price policy there is 50% chance that the seller would sell no unit during the entire selling season (i.e., when $\lambda(p) = \lambda_1(p)$). Hence, the uncertainty on the true demand function and the lack of flexibility of a fixed-price policy to adjust prices over time make this fixed-price policy a risky and suboptimal strategy. To assess the degree of suboptimality, consider the following simple adaptive pricing policy designed to learn the true demand function from early sales. For a fixed $\alpha \in (0, 1)$, let $p_t = p_2$ for all $t \leq \alpha T$. If at least one sale occurs in $[0, \alpha T]$ then set $p_t = p_2$ for all $t \in [\alpha T, T]$, otherwise set $p_t = p_1$ for all $t \in [\alpha T, T]$. The expected

payoff of this pricing policy is given by

$$\begin{aligned} V(x_0, T, \alpha) &= \frac{(1 + e^{-\Lambda \alpha T})}{2} V^{\text{OFP}}(x_0, (1 - \alpha)T) \\ &\quad + \frac{(1 - e^{-\Lambda \alpha T})}{2} \\ &\quad \left(p_2 + 2 \mathbb{E}_\tau [V^{\text{OFP}}(x_0 - 1, T - \tau)] \right), \end{aligned}$$

where $\tau \in [0, \alpha T]$ is a random time with distribution $F_\tau(s) = (1 - e^{-\Lambda s})/(1 - e^{-\Lambda \alpha T})$.

It follows that

$$\begin{aligned} \lim_{x_0 \rightarrow \infty} \frac{V(x_0, T, \alpha)}{V^{\text{OFP}}(x_0, T)} &= \\ 1 + \frac{(1 - \alpha)}{2} (1 - e^{-\Lambda \alpha T}) &\xrightarrow{T \uparrow \infty} 1 + \frac{(1 - \alpha)}{2}. \end{aligned}$$

According to Theorem 3, under full information, a fixed-price policy is asymptotically optimal as x_0 and T grow large. However, in this case with incomplete information, the optimal fixed-price policy can deviate from an optimal strategy by as much as 50% (letting $\alpha \downarrow 0$) as x_0 and T grow large. At the same time, from the bound on $V(x_0, T)$ and the value of $V(x_0, T, \alpha)$ above, it follows that $V(x_0, T, \alpha)/V(x_0, T)$ converges to 1 as x_0 and T grow large and $\alpha \downarrow 0$. This result suggests that under incomplete demand information there could be a version of Theorem 3 stating that an almost everywhere fixed priced policy is asymptotically optimal, that is, a policy in which the seller needs to spend a small amount of time learning and then implementing a fixed-price policy. We will see in the section titled "Minimax and the Regret Function" that such a theorem does indeed exist under rather general conditions.

The previous example reveals the risks that a seller could take if he/she does not fully incorporate the effects of incomplete demand information when selecting optimal pricing strategies. The simple adaptive pricing policy in this example also highlights the new informational role that pricing policies must play when there is uncertainty about the true demand function. With incomplete demand information the seller faces an *exploration-exploitation* trade-off, where the

pricing decision the seller implements incorporates a learning component as part of the revenue maximization problem. In the following section, we summarize a set of theoretical frameworks that have been proposed to incorporate this incomplete demand information in the context of revenue management and dynamic pricing.

DYNAMIC PRICING WITH INCOMPLETE DEMAND INFORMATION

In most (if not all) practical situations, the seller has only partial information about the true value of the demand function $\lambda(p)$. As a result, the dynamic pricing problem (P) needs to be modified to incorporate this additional *ambiguity* in the model formulation. Alternative solutions have been proposed to tackle this problem, which differ in two main characteristics: (i) the representation of the unknown function λ and (ii) the criteria that is used to resolve this model ambiguity.

Regarding the issue of how to model λ , two distinctive approaches have been studied: *parametric* and *nonparametric* models. As suggested by their names, the choice between these two alternatives largely depends on the capacity that the seller has to represent the demand function in terms of a finite number of parameters. To be concrete, suppose that the seller knows that $\lambda \in \mathcal{H}$, where $\mathcal{H}$ is a given family of real-valued functions. If $\mathcal{H}$ is the family of polynomials of degree K (for some fixed K) then $\lambda(p) = \beta_0 + \beta_1 p + \dots + \beta_K p^K$ and the seller's learning problem reduces to estimate the "best" set of parameters $\{\beta_k\}$. On the other hand, if $\mathcal{H} = \mathcal{C}_+[0, \infty)$, the set of nonnegative continuous functions in $[0, \infty)$, then selecting the "best" λ involves searching in this infinite-dimensional space; a problem that does not admit a parametric representation.

Independent of whether the seller uses a parametric or a nonparametric model to represent λ , the question of how to select an optimal pricing strategy needs to be addressed. This problem entails choosing a particular criteria to model how the seller's ambiguity about the true value of λ should impact his/her choice of prices.

The Bayesian approach is probably the most popular alternative used to model sequential demand learning for the case in which λ has a parametric description. Under this approach, model ambiguity on the demand function $\lambda(p)$ is captured by a set of unknown random parameters that characterize this function and for which a prior (at time 0) probability distribution is postulated. As time goes by and the evolution of the demand process is observed, this prior distribution is updated based on the new incoming information using Bayes rule. To be more specific, let θ be a random vector of parameters taking values in a set Θ and let $F(x)$ be the seller's prior probability distribution of θ . For each $\theta \in \Theta$ there is a corresponding demand function $\lambda_\theta \in \mathcal{H}$ and the seller's optimal dynamic pricing problem (P) takes, now, the following form

$$\sup_{p \in \mathcal{A}} \int_{\theta \in \Theta} \mathbb{E} [\mathcal{R}(p; x_0; \lambda_\theta)] dF(\theta).$$

From a modeling perspective, the Bayesian method relies heavily on the good judgment and expertise of the decision maker to select (i) the "right" functional form for the demand function and (ii) the "right" prior distribution for the unknown parameters. There are positive and negative sides to this approach. On the negative side, the parametric nature of the Bayesian model confines the demand learning within the boundaries specified by the proposed functional form and prior distribution and so any misspecification on these quantities will persist throughout the entire learning process. On the positive side, the Bayesian approach benefits from any prior knowledge that the decision maker may have about the demand process. This knowledge is particularly beneficial in those cases where the planning horizon is relatively short and there is limited time to learn through experimentation. Finally, Bayesian models can be mathematically tractable (with computationally efficient solution methods) for some specific family of distributions of the prior (those families of distributions for which their *conjugate* is tractable). In the section titled "Dynamic Pricing with Bayesian Learning", we review some representative papers that use this Bayesian method.

As mentioned above, one valid criticism to the Bayesian approach is its strong dependence on the existence of a prior probability distribution for θ . Rather than modeling these unknown parameters as random variables, an alternative approach is to use a point estimate $\hat{\theta} \in \Theta$, where the value of $\hat{\theta}$ is determined by optimizing a particular criteria that depends on θ and all available information. For example, at time $t = 0$, the *maximum likelihood estimation* of $\hat{\theta}$ solves

$$\hat{\theta} := \operatorname{argmax}_{\theta \in \Theta} \mathcal{L}(\theta, \mathcal{F}_0),$$

where $\mathcal{L}(\theta, \mathcal{F}_0)$ measures the likelihood of observing a history $\mathcal{F}_0$ for a given value of $\theta \in \Theta$. In other words, the seller's model ambiguity is resolved by mean of an optimization problem in terms of a likelihood objective function. Alternative estimation criteria have been proposed, essentially by replacing $\mathcal{L}$ by other objective functions such as *least square estimation* (or more generally $\|\cdot\|_q$ -norm estimation), or *minimum entropy estimation*. As opposed to the Bayesian approach in which the exploration and exploitation stages are conducted simultaneously, in these models both steps are often decoupled. That is, given an estimate $\hat{\theta}$, the seller determines an optimal pricing strategy by maximizing expected revenue, $\mathbb{E}[\mathcal{R}(p; x_0; \lambda_{\hat{\theta}})]$. On the other hand, demand learning is achieved by periodically recomputing the value of $\hat{\theta}$ as new information is gathered, that is, replacing $\mathcal{F}_0$ by $\mathcal{F}_t$ as time goes by. In the section titled "Dynamic Pricing for Linear Demand with Unknown Coefficients", we described a particular example that uses a least square estimation approach.

Another popular approach that has also been used extensively to handle model ambiguity is the class of *robust* formulations. The distinguishing feature of this approach is that it makes no probabilistic assumptions about which function $\lambda \in \mathcal{H}$ is more or less likely to be the true demand function. This *uncertainty set* $\mathcal{H}$ (as it is usually called in this context) captures all the knowledge that sellers have about this demand. A robust pricing strategy is one that guarantees the best possible level of performance (e.g., in a maximin,

competitive ratio, or minimax regret criteria, among others) uniformly over all possible values of $\lambda \in \mathcal{H}$. For example, in the maximin version of problem (P), the seller chooses a dynamic pricing policy that solves for

$$\sup_{p \in \mathcal{A}} \inf_{\lambda \in \mathcal{H}} \mathbb{E}[\mathcal{R}(p; x_0; \lambda)];$$

that is, a pricing policy that maximizes the *worst-case* performance with respect to all demand functions in the uncertainty set $\mathcal{H}$. The popularity of this approach lies in the fact that it captures in a parsimonious way the seller's model ambiguity. In addition, and depending on the characteristics of $\mathcal{H}$ (e.g., polyhedral or ellipsoidal uncertainty sets), the maximin formulation can be solved efficiently. Among the disadvantages, the maximin criteria generally produce solutions that are too conservative, specially if $\mathcal{H}$ is "big." For instance, suppose that $\mathcal{H}$ contains a function λ_{ϵ} such that $\lambda_{\epsilon}(p) = 0$ for all $p \geq \epsilon$ for some $\epsilon > 0$ small. Then, an optimal maximin pricing policy satisfies $p_t^* < \epsilon$ for all t . It follows from this example that one needs to take special care in selecting the set $\mathcal{H}$ under a maximin objective in order to avoid trivial or nonrealistic solutions. To address this issue of conservatism, other robust criteria have been proposed. For example, under an absolute minimax regret approach the seller selects a pricing policy that minimizes the difference in performance with respect to the full information case

$$\inf_{p \in \mathcal{A}} \sup_{\lambda \in \mathcal{H}} \left\{ \sup_{\tilde{p} \in \mathcal{A}} \mathbb{E}[\mathcal{R}(\tilde{p}; x_0; \lambda)] - \mathbb{E}[\mathcal{R}(p; x_0; \lambda)] \right\}.$$

Note that in this case, it is not generally true that an optimal pricing policy is conditioned by the presence of λ_{ϵ} in $\mathcal{H}$.

Another disadvantage of the robust approach—one that is particularly relevant in our present discussion—is that it does not explicitly incorporate the possibility of demand learning. In the section titled "Minimax and the Regret Function", however, we review some recent results that show that in certain cases a simple policy that learns for a relatively small period of time and then myopically sets prices is asymptotically optimal in a robust sense.

In the following sections, we discuss some concrete models and examples within the class of parametric and nonparametric models for different demand learning criteria.

PARAMETRIC MODELS

Parametric models are based on some fundamental knowledge that the seller has about the true demand function. For example, the seller might know that $\lambda(p)$ belongs to a specific family of functions, which is characterized by a finite set of parameters (e.g., the family of linear functions as in Ref. 6). The seller parametric sequential learning problem is to identify the “best” value of those parameters using realized market information (prices and sales). As we mentioned above, there are different ways that one can use to identify the best set of parameters that we review in what follows.

Dynamic Pricing with Bayesian Learning

In the context of revenue management and dynamic pricing, there is a growing literature that uses Bayesian models to characterize optimal pricing policies when there is ambiguity about the true demand function. One particular type of uncertainty that has received significant attention is *market size uncertainty*. This model is well suited for those instances of the problem in which the seller knows relatively well consumers’ reservation price distribution $\bar{F}(p)$ but has limited information about the actual size of the population of potential buyers, Λ . Some representative papers that have studied this model are found in Refs 7–9 (see also Refs 10 and 11). In the context of Bayesian learning, Aviv and Pazgal [7] consider the special case in which Λ has a gamma prior distribution and $\bar{F}(p) = \exp(-\alpha p)$ (i.e., exponentially distributed reservation price). The advantage of using a gamma distribution for Λ is that it is a conjugate distribution for the Poisson demand process, which simplifies enormously the use of Bayes rule. In an infinite horizon setting, Farias and Van Roy [8] generalize the demand model in Ref. 7 to the family of finite mixture of gamma distributions and propose a special heuristic (*decay balancing*)

that shows a good numerical performance compared to other heuristics proposed in the literature. In the context of a retail operations, Araman and Caldentey [9] consider an infinite horizon model for an arbitrary $\bar{F}(p)$ and where Λ has a finite support. A distinguishing feature in this model is that the seller has the option to optimally stop selling the product at any given time to switch to a different assortment. This is a particularly valuable option in the context of demand learning since the seller is initially uncertain about how profitable the product really is. For example, if the true value of Λ is small then the seller is better off removing the product.

In what follows, we review the main results of the research discussed in the previous paragraph. The underlying assumption that we make in the reminder of this section is that Λ is the seller’s sole source of uncertainty. Having this in mind, we rewrite Problem (P). We denote by $G_0(\Lambda)$ the seller’s (prior) cumulative probability distribution of Λ at time 0 and by $\mathbb{P}_0(\mathbb{E}_0)$ the conditional probability measure (expectation operator) given G_0 . We define similarly G_t , $\mathbb{P}_t$, and $\mathbb{E}_t$ conditional on $\mathcal{F}_t$, the available information at time t . Using a slight abuse of notation, let $r(p) = p \bar{F}(p)$. The seller’s problem is given by

$$\sup_{p \in \mathcal{A}} \mathbb{E}_0 \left[\int_0^T \Lambda r(p_t) dt \right]$$

subject to and

$$\int_0^T dN_t^p \leq x_0 \quad (a.s.). \quad (\text{B})$$

Similar to Problem (P), we can solve Problem (B) using dynamic programming but with an enlarged state space (x, t, G_t) . The parametric description of G_t comes in handy at this point to ensure the tractability of the resulting dynamic programming (DP) algorithm.

The stochastic evolution of the new state variable G_t is derived from Bayes rule. For the sake of concreteness, let us suppose that Λ has a finite support $\{\Lambda_k\}_{k=1}^K$ (where $\{\Lambda_k\}$ is an increasing sequence) so that G_t is piecewise constant. Let $g_t(k) = G_t(\Lambda_k) - G_t(\Lambda_{k-1})$ with $\Lambda_0 = 0$. Then, the Bayes rule implies

that (see Proposition 3 and Section 6.1 in Ref. 9 for details)

$$g_t(k) = \mathbb{P}_0(\Lambda = \Lambda_k | \mathcal{F}_t) = \frac{g_0(k) \cdot (\Lambda_k I_t^p)^{N_t} \exp(-\Lambda_k I_t^p)}{\sum_j g_0(j) \cdot (\Lambda_j I_t^p)^{N_t} \exp(-\Lambda_j I_t^p)}.$$

It follows from its definition that $\{g_t, \mathcal{F}_t\}$ is a martingale. Application of Itô's lemma in the previous equation leads to the following stochastic differential equation (SDE)

$$dg_t(k) = \eta_k(g_t) (\lambda_t \bar{\Lambda}(g_t) dt - dN_t), \quad 1 \leq k \leq K,$$

$$\text{where } \bar{\Lambda}(g) := \sum_k g(k) \Lambda_k \text{ and}$$

$$\eta_k(g) := g(k) \left(\frac{\bar{\Lambda}(g) - \Lambda_k}{\bar{\Lambda}(g)} \right).$$

The resulting HJB optimality condition for Problem (B) is given by

$$\begin{aligned} \frac{\partial}{\partial t} V(x, t, g) = \max_p \left[\bar{\Lambda}(g) \bar{F}(p) [V(x-1, t, g - \eta(g)) - V(x, t, g) + \eta(g) \right. \\ \left. \cdot \nabla_g V(x, t, g)] + \bar{\Lambda}(g) r(p) \right], \quad (2) \end{aligned}$$

where $\nabla_g V(x, t, g)$ is the gradient of $V(x, t, g)$ with respect to g . The boundary conditions are $V(0, t, g) = V(x, 0, g) = 0$ and $V(x, t, e_k) = J_1^*(x, \Lambda_k t)$ where e_k is the distribution that gives probability one to the event $\{\Lambda = \Lambda_k\}$ and $J_1^*(x, t)$ is the full information value function for problem (P) when the market size is normalized to one. Note that the latter border condition follows from Theorem 2. Solving Equation (2) is usually a very difficult task because of the singularities at the boundary points $g = e_k$ and the jumps in x and g that make the HJB a delayed difference-differential equation. Despite the fact that an analytical solution is not immediately available, this optimality condition provides enough information to derive some useful properties that we can use to approximate the value function and the corresponding pricing strategy.

Theorem 4. *The value function $V(x, t, g)$ satisfies the following properties:*

- (i) *It is increasing in x and t . It is also convex in g .*
- (ii) *It is bounded by: $J^*(x, \Lambda_1 t) \leq V(x, t, g) \leq \sum_k g(k) J^*(x, \Lambda_k t) \leq J^*(x, \bar{\Lambda}(g) t)$.*
- (iii) *It satisfies $\lim_{x \rightarrow \infty} V(x, t, g) = \bar{\Lambda}(g) r(p^*)$ $t = \lim_{x \rightarrow \infty} \sum_k g(k) J^*(x, \Lambda_k t)$. The optimal price satisfies $\lim_{x \rightarrow \infty} p^*(x, t) = p^*$.*
- (iv) *A fixed-price policy is asymptotically optimal in the following sense. Let $V^{\text{FP}}(x, t, g)$ be the seller's expected revenue using an optimal fixed-price for the entire sale horizon. Then,*

$$\begin{aligned} 1 - \frac{1}{2\sqrt{\min\{x, \bar{\Lambda}(g) \bar{F}(p^*) t\}}} \\ \leq \frac{V^{\text{FP}}(x, t, g)}{V(x, t, g)} \leq 1. \end{aligned}$$

Proof. Part (i). The monotonicity of $V(x, t, g)$ on t and x follows trivially from its definition. The convexity on g follows from

$$\begin{aligned} V(x, t, g) = \sup_p \mathbb{E} \left[\sum_k g(k) \int_0^T p_t dN_t^p(k) \right], \\ \text{where } N_t^p(k) := \mathcal{N} \left(\Lambda_k \int_0^t \bar{F}(p_s) ds \right). \end{aligned}$$

Part (ii). The first inequality (lower bound) follows from implementing on the incomplete information case, the optimal pricing policy for the case of full information with $\Lambda = \Lambda_1$. The second inequality follows from interchanging the sup and the summation in the equation above. The third inequality follows from Theorem 2. Part (iii) follows from noticing that for $x = \infty$, the optimal pricing strategy is $p_t = p^*$, which maximizes the instantaneous revenue rate (see the discussion in the section titled "Dynamic Pricing with Complete Demand Information" after the definition of Problem (P)) independently of the value of Λ . Finally, Part (iv) follows from combining the upper bound on Part (ii) and the result in Theorem 3.

Note that $\mathbb{E}[J^*(x, \Lambda, t)] = \sum_k g(k) J^*(x, \Lambda_k, t)$ and so point (ii) asserts that an upper bound for the value function is given by the expected value (over the unknown market size Λ) of the full information value function. Point (iv) extends Gallego and van Ryzin's [5] result in Theorem 3 to the case with uncertain market size. This result suggests that the lack of asymptotic optimality of a fixed-price policy that we identified in Example 1 is mainly due to the seller's uncertainty about the buyer's reservation price distribution rather than the actual market size.

Approximations and Heuristics. One approach that has been used to approximate the optimal pricing policy is to first get an approximation of the value function and then plug it in the HJB equation (2) to derive an approximating pricing policy. For any approximation $V^{\text{aprx}}(x, t, g)$ of the value function, the corresponding pricing policy is given by

$$p^{\text{aprx}}(x, t, g) = \zeta \left(V^{\text{aprx}}(x-1, t, g - \eta(g)) - V^{\text{aprx}}(x, t, g) + \eta(g) \cdot \nabla_g V^{\text{aprx}}(x, t, g) \right), \quad (3)$$

the function ζ was defined in the section titled "Dynamic Pricing with Complete Demand Information". (It should be clear that the pair $(V^{\text{aprx}}, p^{\text{aprx}})$ does not solve Equation (2).) This approach was used in Ref. 9 to derive an *asymptotic approximation*. This policy is based on the observation that points (ii) and (iii) in Theorem 4 suggest the use of the following approximation for the value function $\tilde{V}(x, t, g) = \sum_{k=1}^K g(k) J^*(x, \Lambda_k, t)$, which is asymptotically optimal as x grows large. Let us denote by $\tilde{p}(x, t, g)$ the pricing policy that results from using $\tilde{V}(x, t, g)$ in Equation (3).

An alternative approach to approximate an optimal pricing policy is to solve a modified version of the HJB equation. A popular example is the so-called *naïve policy*. This approximation assumes that at every state (x, t, g) the seller solves the full information HJB in Equation (1) replacing the unknown Λ by its expected value $\bar{\Lambda}(g)$ (see Ref. 7 for details). Another example is the *decay balancing heuristic* proposed by Farias and Van

Roy [8]. Although this policy was derived in an infinite horizon setting, the main idea can be directly extrapolated to the finite horizon case. The decay balance policy combines the asymptotic policy $\tilde{V}(x, t, g)$ and the HJB equation (2) (see also Equation (1)) to propose a pricing policy $p^{\text{BD}}(x, t, g)$ solution to

$$\frac{\partial}{\partial t} V(x, t, g) = \bar{\Lambda}(g) \frac{\bar{F}(p^{\text{BD}}(x, t, g))}{h(p^{\text{BD}}(x, t, g))}.$$

Under the additional assumption that the reservation price distribution, $F(p)$, has increasing failure rate, the solution $p^{\text{BD}}(x, t, g)$ is unique. A set of numerical experiments comparing the *asymptotic approximation*, the *naïve policy*, and the *decay balancing heuristic* is reported in Ref. 8.

Dynamic Pricing for Linear Demand with Unknown Coefficients

The Bayesian method, as discussed in the previous section, relies heavily on the seller's prior distribution of the unknown parameters. In those cases, when no prior exists, the seller must rely on an alternative statistical estimation method, such as the least square estimator (LSE), the maximum likelihood estimator (MLE), the minimum entropy estimator (MEE), and others. Some representative examples are Ref. 6 (this model is discussed in more detail below), Ref. 12, which considers also a linear price demand function and obtains approximate solutions using convex programming methods, and Ref. 13. Carvalho and Puterman [13] consider a binomial demand, which is relevant in the internet environment representing those that visited a web site and ended up buying the item. Under such a demand model, some parameters are unknown and a Monte Carlo simulation is used to quantify the trade-off between learning and revenue maximization. This simulation allows to measure the performance of few suggested heuristics among others, the one-step-look-ahead policy. Because of the numerical flavor, the method could apply to various estimation techniques in particular maximum likelihood and Bayes.

Bertsimas and Perakis [6] consider a discrete variant of problem (P) in which the demand in every period n is given by

$$d_n = \beta^0 + \beta^1 p_n + \epsilon_n,$$

where the ϵ_n 's are iid $(0, \sigma^2)$ normal random variables. The parameters β_0, β_1 , and σ are unknown. The estimates at period n of these parameters are computed using the LSE method

$$\begin{aligned} (\hat{\beta}_n^0, \hat{\beta}_n^1) &= \arg \min_{\mathbf{r} \in \mathbb{R}^2} \sum_{s=1}^{n-1} (d_s - \mathbf{x}'_s \mathbf{r})^2 \quad \text{and} \\ \hat{\sigma}_n^2 &= \sum_{\tau=1}^{n-1} \frac{(d_\tau - \hat{\beta}_n^0 - \hat{\beta}_n^1 p_\tau)^2}{n-3} \\ n &= 4, \dots, T, \end{aligned}$$

where, $\mathbf{x}'_s = [1, p_s]$. At the beginning of period n , the decision variable p_n is selected to maximize the total expected revenue-to-go. To compute this revenue-to-go, the seller needs to estimate the distribution of the demand in period $s \geq n$ (denoted by $\hat{d}_{s,n}$) conditional on the current estimates $(\hat{\beta}_n^0, \hat{\beta}_n^1, \hat{\sigma}_n)$. It follows that $\hat{d}_{s,n} = \hat{\beta}_{s,n}^0 + \hat{\beta}_{s,n}^1 p_s + \hat{\epsilon}_{s,n}$, where, $\hat{\epsilon}_{s,n}$ is a normally distributed random variable with mean 0 and standard deviation $\hat{\sigma}_{s,n}$; we use the notation $\hat{y}_{s,n}$ to denote the current period n estimate of a parameter y for a future period s , $s = n, \dots, T$. The most critical step in this approach (similar to the Bayesian case) is to obtain an iterative process that, given a state space, computes future estimates. It can be shown that the evolution of these estimates is given by

$$\hat{\beta}_{s+1,n}^i = \hat{\beta}_{s,n}^i + \hat{\epsilon}_{s,n} \cdot h_i \left(p_s, \sum_{\tau=1}^{s-1} p_\tau, \sum_{\tau=1}^{s-1} p_\tau^2 \right),$$

for $i \in \{0, 1\}$, and

$$\begin{aligned} \hat{\sigma}_{s+1,n}^2 &= \mathcal{H} \left(p_s, \hat{\beta}_{s,n}^0, \hat{\beta}_{s,n}^1, \sum_{\tau=1}^{s-1} p_\tau^2, \sum_{\tau=1}^{s-1} p_\tau, \right. \\ &\quad \left. \sum_{\tau=1}^{s-1} p_\tau d_\tau, \sum_{\tau=1}^{s-1} d_\tau, \hat{\sigma}_{s,n}^2 \right), \end{aligned}$$

for some real functions h_i and $\mathcal{H}$ (see Ref. 6 for details). These estimates are used in a DP

formulation where the state space is given by the vector

$$\mathbf{X}_s = \left(x_s, \hat{\beta}_{s,n}^0, \hat{\beta}_{s,n}^1, \sum_{\tau=1}^{s-1} p_\tau^2, \sum_{\tau=1}^{s-1} p_\tau, \sum_{\tau=1}^{s-1} p_\tau d_\tau, \sum_{\tau=1}^{s-1} d_\tau, \hat{\sigma}_{s,n}^2 \right),$$

where x_n is the inventory available in period n . At each period n , one solves the following DP with

$$\begin{aligned} J_T(c_T, \hat{\beta}_{T,n}^0, \hat{\beta}_{T,n}^1, \hat{\sigma}_{T,n}^2) &= \max_{p_T} \mathbb{E}_{\epsilon_{T,n}} p_T \\ &\quad \min \left\{ (\beta_{T,n}^0 + \beta_{T,n}^1 p_T + \epsilon_{T,n}), c_T \right\}, \end{aligned}$$

and for $s = n, \dots, T-1$,

$$\begin{aligned} J_s(\mathbf{X}_s) &= \max_{p_s} \mathbb{E}_{\epsilon_n} \left[p_s \min \left\{ \hat{\beta}_{s,n}^0 + \hat{\beta}_{s,n}^1 p_s \right. \right. \\ &\quad \left. \left. + \hat{\epsilon}_{s,n}, c_s \right\} + J_{s+1}(\mathbf{X}_{s+1}) \right], \quad (4) \end{aligned}$$

where the components of $\mathbf{X}_{n+1}$ get updated based on the selected value of p_s , the corresponding demand estimate and the iterative processes described above (e.g., $c_{s+1} = c_s - \min\{\hat{\beta}_{s,n}^0 + \hat{\beta}_{s,n}^1 p_s + \hat{\epsilon}_{s,n}, c_s\}$).

A few observations are in order. First, we note that for a fixed n , the sequence $(\hat{\beta}_{s,n}^i : s = n, \dots, T)$ made of the estimates at time n for future values of the parameter is a stochastic process and in particular a martingale. This is an expected fact as it measures the learning process. A valid question at this point is how to possibly quantify the learning. It will be hard to obtain a tractable formulation of the gap between the optimal values and those obtained through the estimation process, but a Monte Carlo simulation can help in this regard. Similar to Ref. 13, one can solve for the optimal pricing policy under known parameters β_0, β_1 and σ and then implement the previous pricing policy obtained through the learning process.

The main characteristic of this problem is the concurrent parameter estimation and the pricing optimization (active learning). If we decouple these two actions (move to passive learning), whereby the pricing

decision made at time n is assumed not to affect the parameter estimates at time $n + 1$, then the state space of the DP can be reduced to one dimension, that of the available capacity.

The setting of Ref. 6 is similar to the initial problem (P). The difference, beyond the fact that time is discrete, is the choice itself of a linear demand rate with a normally distributed error term independent of the price. From a practical standpoint, this model fits well with the popular approach of forecasting demand using linear regressions. Another advantage of this model compared to those discussed in the section titled “Dynamic Pricing with Bayesian Learning” is that the learning process includes the price elasticity (i.e., an unknown reservation price distribution) as well as the market size. From a modeling perspective, the choice of a normally distributed demand could potentially lead to estimation errors if the probability of a negative demand is not negligible (e.g., low moving items). One possible way to take care of this problem without losing tractability is to consider a log-normal where $d_n = a \exp(\beta^0 + \beta^1 p_n + \epsilon_n)$ so that by taking logarithm we recover a linear model (see Ref. 14 for a discussion of related demand model in the context of retail operations).

NONPARAMETRIC MODELS: MAXIMIN AND MINIMAX METHODS

Nonparametric models are concerned with settings where the form of the demand function is not known. We distinguish two classes of nonparametric models. A first one is known as the *maximin approach*. Such criterion induces the optimizer, to maximize the worst-case profit. It is a very conservative approach. This conservatism can be reduced by introducing a carefully chosen “budget” of uncertainty, which limits the set of possible distributions or demand functions [15,16]. Many papers have applied this method in operations management contexts [17], while Ref. 18 applied it specifically to the setting discussed in this article. The other class of nonparametric models is known as the

minimax approach whereby a regret function is introduced that measures the performance of a policy relative to the performance of the optimal policy under a fully known demand function. This approach is less conservative than the maximin and has also been applied to various settings including, recently, to revenue management. We refer the reader to Refs 19–21 and references therein. The first two papers consider a single resource allocation problem and the latter analyzes a network revenue management. In the last section of this article, we discuss in some detail some of these approaches.

Learning is a dimension that is often missing in robust models. Indeed, most of the papers cited above, disregard learning and study an optimization problem that constrains the unknown demand function to some static, prespecified, (nonparametrized) set. Having said that, there exist nonparametric models that do rely on exploiting demand realizations in order to learn the demand function and shape the solution of the optimization problem. Understandably, this approach happens to have more of an algorithmic flavor; see for instance Refs 22 and 23 and (more relevant to our setting) [24,25]. We discuss in more detail the model of Besbes and Zeevi [25], which considers, specifically, problem (P), and relies on learning while using a minimax formulation. The approach used in Ref. 18 will also be discussed below as an application of the maximin criteria applied to problem (P).

Consider again the general formulation (P) of the model. As mentioned in the introduction, the expected value is taken with respect to the probability measure defined on the Poisson process filtration. In both the Bayesian and the demand estimation approaches, the unknown parameters were replaced by their estimate and the probability measure was adjusted accordingly (e.g., in the Bayesian case, $\mathbb{P}$ is replaced by $\mathbb{P}_g$, while in the demand estimate case, $\mathbb{E}$ is replaced by $\mathbb{E}_\epsilon$). Consider now the case where the demand belongs to a nonparametric class of functions. The fact that the demand intensity is unknown makes the seller’s maximization problem (P) ill-defined. In order to

overcome this first challenge, a maximin or a minimax formulation has been proposed, which transforms the problem into a stochastic game. The seller still has to choose a pricing policy and in response, nature (or a clairvoyant adversarial agent) picks the “worst” possible demand function given the seller’s choice. The (real) demand function that is unknown is replaced by the solution of an optimization problem. In other words, the seller selects the pricing policy to guarantee, somehow, the best worst-case performance.

In mathematical terms, the seller’s maximin formulation of problem (P) is given by

$$\begin{aligned} & \sup_{p \in \mathcal{A}} \inf_{\lambda \in \mathcal{H}} \mathbb{E} \left[\int_0^T p_t \lambda(p_t) dt \right] \\ & \text{subject to} \quad N_\lambda^p(T) \leq x_0 \quad (\text{a.s.}), \quad (\text{M}) \end{aligned}$$

where $\mathcal{H}$ is the (possibly infinite-dimensional) set of functions that contains the true demand function.

Maximin and the Relative Entropy Formulation

A maximin approach as presented in the section titled “Dynamic Programming with Incomplete Demand Information”, induces the seller to select the price that will maximize the worst-case expected total revenues: a worst case with respect to the demand functions and the pricing policy adopted. Reducing the conservatism of this approach entails reducing the uncertainty set or the set of possible demand functions. We follow here the approach in Ref. 18, to suggest a robust formulation of Problem (P).

In the setting of problem (P), there is a one-to-one relationship between the demand function $\lambda(\cdot)$ of the Poisson process and the probability measure $\mathbb{P}$ governing the system. Hence, the set of demand functions can be replaced by a set of probability measures and it is in the interest of the seller to pick carefully this set as it will dictate how conservative the solution will be.

Often it is the case that the seller has collected information (through historical data) on the “real” demand function he/she is or will be facing. This information is represented as

a demand function, $\beta(\cdot)$, that is not necessarily the real (and still unknown) demand function $\lambda(\cdot)$. However, with some confidence one can assume that both demand rates are not too “far” apart. We denote by $\mathbb{P}$ (respectively $\mathbb{Q}$) the probability measure induced by a demand rate $\lambda(\cdot)$ (respectively $\beta(\cdot)$). The set of probability measures $\mathbb{P}$ close to $\mathbb{Q}$, from which a clairvoyant will draw the worst possible measure, is defined as follows:

- $\mathbb{P}$ is absolutely continuous with respect to $\mathbb{Q}$, denoted by $\mathbb{P} \ll \mathbb{Q}$.
- $\mathbb{P}$ satisfies $\mathcal{E}(\mathbb{P} | \mathbb{Q}) \leq \gamma$, where $\mathcal{E}(\mathbb{P} | \mathbb{Q}) := \mathbb{E}_{\mathbb{P}} \ln \eta(T)$ and $\eta(T)$ is the Radon–Nikodym derivative of $\mathbb{P}$ with respect to $\mathbb{Q}$ [3]. The function $\mathcal{E}$ is known as the *relative entropy* of $\mathbb{P}$ with respect to $\mathbb{Q}$ and γ is some positive constant (sometimes referred to as the *budget of uncertainty*) that captures the seller’s confidence level about how close the true probability measure is to the nominal measure $\mathbb{Q}$ (in a relative entropy sense).

These two conditions define an *uncertainty set* of probability measures. Note that for $\gamma \equiv 0$, this set reduces to $\{\mathbb{P} \equiv \mathbb{Q}\}$.

We consider the following transformation of problem (P) and a variant of problem (M) under a maximin criterion

$$\begin{aligned} J(x, T) &= \sup_p \inf_{\mathbb{P} \ll \mathbb{Q}} \mathbb{E}_{\mathbb{P}} \int_0^T p(t) dN(t) \\ & \text{subject to} \quad \mathcal{E}(\mathbb{P} | \mathbb{Q}) \leq \gamma. \end{aligned}$$

Using Girsanov’s Theorem applied to point processes [3], one can prove that there is a stronger correspondence between probability measures in the uncertainty set defined above and their intensities. In particular, the Poisson process with rate $(\lambda(p_t) : t \geq 0)$ under the (unknown) probability measure $\mathbb{P}$ is a Poisson process under the nominal probability measure $\mathbb{Q}$ but with an intensity $(\beta(p_t)\kappa(t) : t \geq 0)$ where $\kappa(\cdot)$ is some (unknown) nonnegative process. Hence, instead of picking $\mathbb{P}$, it is enough for nature to pick κ under $\mathbb{Q}$. With this alternative formulation, one can solve the seller’s

problem using dynamic programming. The corresponding HJB equation is given by

$$\begin{aligned} \frac{\partial}{\partial t} J(x, t) \\ = \max_p \min_{\kappa} \left\{ \lambda(p) [p\kappa + \theta (\kappa \log \kappa + 1 - \kappa)] \right. \\ \left. + \lambda(p)\kappa [J(x-1, t) - J(x, t)] \right\}, \end{aligned}$$

with border conditions $J(x, 0) = J(0, t) = 0$ and where the constant θ is fully characterized given γ (see Ref. 18 for details). One interesting feature of this equation is the interchangeability of min and max under strong concavity of the nominal revenue rate. Moreover, as in Ref. 5, a closed-form solution can be obtained for an exponential demand function (see Ref. 18 for details).

Minimax and the Regret Function

The recent work of Besbes and Zeevi [25] studies a minimax variant of problem (M). In particular, it considers a rather general nonparametric uncertainty set $\mathcal{H}$, which is the set of uniformly bounded and Lipschitz continuous functions with bounded support. A relative regret function, $\mathcal{M}$, is defined as one minus the ratio between the value function, $J^p(x, t; \lambda)$ (generated by any pricing policy p) and the value function in the deterministic case, $J^D(x, t; \lambda)$ (conditioned on knowing the true demand function λ),

$$\mathcal{M}^p(x, t; \lambda) := 1 - \frac{J^p(x, t; \lambda)}{J^D(x, t; \lambda)}.$$

This regret function is inspired by two results in Ref. 5 (see Theorem 3) that establish that (i) the value function under a deterministic demand upper bounds the value function under a Poisson demand and (ii) a fixed-price policy, solution of the deterministic problem, is asymptotically optimal. Hence, the regret function is nonnegative and bounded by 1 (independently of λ), and measures the performance of a pricing policy p for a specific demand function λ . The smaller the regret is, the better the pricing policy is, taking the value zero only when the pricing policy is able to achieve the value of the deterministic

setting. At this point, it remains to transform the initial problem formulation into a stochastic game, where the seller chooses the “optimal” pricing policy taking into consideration that nature will then pick the worst possible demand curve (i.e., by maximizing the regret). The minimax *relative* regret formulation is written as follows

$$\inf_{p \in \mathcal{P}} \sup_{\lambda \in \mathcal{H}} \mathcal{M}^p(x, t; \lambda).$$

For any pricing policy p the inner maximization problem is (at least in theory) well defined. Solving the previous problem is in general not possible. One approach would be to construct a pricing policy that performs well. As we recalled in Theorem 3, when the demand function is known, say $\tilde{\lambda}$, a fixed-price policy $p_t = p^D(\tilde{\lambda})$ is asymptotically optimal in the context of Ref. 5. In the case where the demand curve is unknown, Besbes and Zeevi [25] propose a policy that aims at estimating, first, the demand function λ and then fix the price to be equal to $p^D(\lambda)$. Specifically, they explore, first, how demand reacts to a set of selected prices (passive learning phase) and then exploit this learning to get approximations of both the run-out price, p^0 and the maximizer of the demand function, p^* . (See the discussion that precedes Theorem 3 for the definitions of p^0 and p^* .) In the second phase, they adopt a fixed price policy, which is the minimum of the two approximated prices. The longer the learning phase is, the more accurate the price approximations are; but the higher the opportunity cost is (due to the nonoptimal pricing during the learning phase). Algorithm 1 is sensitive to the length of the learning period τ and to a granularity parameter κ and follows the following steps. (i) In the *initialization* step, κ prices are picked equidistantly from the interval of possible prices $[\underline{p}, \bar{p}]$. The interval $[0, \tau]$ is divided in κ equal time intervals, $\Delta = \tau/\kappa$. (ii) In the *learning/experimentation* step, each of the κ preselected prices is applied on one of the κ intervals of time of length Δ . Demand gets realized accordingly and at the end of this phase, the total demand realized in each of these intervals is computed; each demand value is divided by Δ thus representing an

approximation of the demand rate function $\hat{d}(p_i)$ at the price selected for that interval. The approximated demand rate is in turns multiplied by the price and the result, $\hat{d}(p_i) \cdot p_i$, is an approximation of the revenue rate at that price. At the end of these two steps, κ points approximating the demand and the revenue rate functions have been gathered. (iii) The *optimization* step identifies two specific prices

$$\hat{p}^u = \arg \max_{1 \leq i \leq \kappa} \{\hat{d}(p_i) \cdot p_i\}, \quad \text{and}$$

$$\hat{p}^c = \arg \min_{1 \leq i \leq \kappa} \{\hat{d}(p_i) - x/T\}.$$

(iv) In the last *pricing* step, the price $\hat{p} = \hat{p}^u \wedge \hat{p}^c$ is applied on the interval $(\tau, T]$. We denote by $p(\tau, \kappa)$ the output of Algorithm 1. In terms of performance, this policy is shown to be asymptotically optimal in the following sense.

Proposition 1. *Set $\tau_x = x^{-1/4}$, $\kappa_x = x^{1/4}$ and let $p_x := p(\tau_x, \kappa_x)$ be given by Algorithm 1. Then the sequence $\{p_x\}$ is asymptotically optimal, and for all $x \geq 1$*

$$\frac{C'}{x^{1/2}} \leq \sup_{\lambda \in \mathcal{H}} \mathcal{M}_x^p(x; \lambda) \leq \frac{C(\log x)^{1/2}}{x^{1/4}},$$

for some positive constant C and C' .

The lower bound (in fact obtained under slightly stronger assumptions) measures the decreasing gap between Algorithm 1 and the optimal solution.

Clearly, this approach can also be applied to the case where the demand function belongs to a parameterized set $(\lambda(\cdot; \eta) \in \mathcal{H}_\eta)$, as it was the case in both the Bayesian and the demand estimate methods. It is easily shown that the pricing policy generated by Algorithm 1 remains asymptotically optimal. The example in the section titled “Dynamic Pricing with Complete Demand Information” is a good illustration of such a setting and how effective is a pricing policy driven by a short learning period followed by a fixed price policy. Moreover and as expected, Algorithm 1’s performance improves in the parameterized case. The corresponding upper bound of Proposition 1 is tighter and the number

of pricing test points during the learning phase is set equal to the number of unknown parameters (i.e., bounded and generally small). Such an interesting result requires that the parameterized demand function satisfies additional regularity assumptions. It needs to be “identifiable” based on a set of observations, which in particular means that for any vector $d = (d_1, \dots, d_k)$, the system of equations $\{\lambda(p_i; \eta) = d_i, i = 1, \dots, k\}$ has a unique solution in η .

Nonparametric approaches relying on robust controls, as we saw above, do not follow so much a general framework or methodology as much as their parametric counterparts do (e.g., Bayesian or statistical estimation methods). Nonparametric approaches are stemmed essentially from the specific model under study. In order to have a broader sense of the different techniques that could be used, we discuss in the next section another revenue management setting that has recently been analyzed in the context of robust controls. Again, the main drawback of these approaches is the lack of learning. They do induce robust decisions, however the realizations of demand are not being incorporated in any way to reduce the uncertainty set.

Robust Single-Leg Revenue Management Model

The so-called single-leg model is to revenue management what the newsboy model is to inventory management. (A broad literature is available on this subject and is very well summarized in Ref. 2.) The setting in this single-leg revenue management model is almost identical to the dynamic pricing model that we have discussed so far with one notable difference; items can be sold at different prices at the same time. The canonical example corresponds to seats in an airplane that, depending on the different restrictions that the airline imposes on the products (e.g., refundable vs nonrefundable tickets), are sold at different fares. These fare classes are typically announced at time 0 and remain fixed throughout the entire selling season. In this setting, the seller, rather than controlling a single price over time, selects dynamically which fare classes to *open* and which ones to *close* as a function of the available inventory

and remaining sale horizon. Nonparametric methods have been used recently in the literature to formulate and solve this “cousin” version of Problem (P).

As before, let x_0 be the seller’s initial inventory and let $f_1 > f_2 > \dots > f_m$ be the fares associated to the m different products offered by the seller. We assume that every product consumes one unit of inventory. (In the general setting of *network revenue management*, the seller is endowed with a collections of different resources and different products consume a combination of resources in different quantities.) The seller’s objective is to select an admission control policy π that specifies which fare classes to accept (open) and which ones to reject (close) based on the state of the system at every point in time. A renowned strategy is the *standard nesting* policy, which works as follows. The seller selects *booking limits* $(\theta_1, \theta_2, \dots, \theta_m)$ associated to the m fare classes, such that $\theta_1 \geq \theta_2 \geq \dots \geq \theta_m$. A class- j request is accepted (i.e., to whom one unit of resource is sold at f_j) only if the number of customers of classes j to m (i.e., corresponding to fare f_j or lower) already accepted is less than or equal to θ_j .

Ball and Queyranne [19] analyze this problem in an environment where demand information is incomplete using critical ratio ideas, which are popular in the context of competitive analysis for on-line algorithms (see Ref. 26 for a survey on the subject). We denote by $R^\pi(I)$ the revenues generated by applying some policy π to a stream of arrivals, I . We call this an “on-line algorithm.” We let $R^*(I)$ be the revenues obtained by applying the best possible policy for that particular stream of arrivals I . This is the “off-line algorithm,” that is, revenues that can be achieved if the seller selects the policy after he/she sees the entire stream of arrivals. An on-line algorithm can be deterministic (i.e., for a specific stream of demand the output is deterministic) or randomized (i.e., for a specific stream of arrivals, the output depends on the outcome of some random variable). We refer the reader to Ref. 20 for a brief discussion of randomized policies.

We let Ω_π be the set of all possible demand streams I that a policy π can face and define the competitive ratio as

$$\Upsilon(\pi) := \inf_{I \in \Omega_\pi} \frac{\mathbb{E}R^\pi(I)}{R^*(I)}.$$

We denote by c^* the supremum of Υ on all possible (deterministic or randomized) policies π . It is not hard to see that by maximizing the competitive ratio we are minimizing the worst-case relative regret $\sup [1 - \mathbb{E}R^\pi(I)/R^*(I)]$. We should also note that computing c^* requires a pathwise deterministic optimization, as the expected value is only with respect to the possibly randomized algorithm π . This relative regret formulation is different from the one defined in Ref. 25. In the latter, the denominator of the regret function was the value function under a deterministic demand. In a competitive ratio setting, the denominator is a function of the specific stream of arrivals. These two denominators are asymptotically the same in the case of Problem (P) when the demand function is known.

The competitive ratio of a particular policy π , measures its Performance, which is to be compared to c^* . In particular, a policy that achieves c^* is optimal. Ball and Queyranne [19] use this method to evaluate c^* for a multifare single-leg problem and show that

$$c^* = \left(m - \sum_{j=2}^m \frac{f_j}{f_j - 1} \right)^{-1}.$$

It is also shown that standard nesting policies achieve c^* (and hence are optimal under a competitive ratio criterion) when the (nested) booking limits, θ_j ’s are given by

$$\theta_j = x_0 - \frac{x_0}{c^*} \left(j - \sum_{i=1}^j \frac{f_{i+1}}{f_i} \right).$$

The approach adopted to prove such a result is as follows. One first recognizes the optimal policy, (e.g., the standard nesting) and calculates its optimal competitive ratio (e.g., find the best possible booking limits). It remains then to show that this competitive ratio is the best achievable among all

other (deterministic or randomized) policies. The first step is proven by dissecting all possible arrival streams with respect to the candidate policy. The most critical step is the second one that often relies on a powerful result, the Neuman–Yao principle, which states that

$$c^* \geq \sup_{\pi_d} \mathbb{E}_Q \frac{R^{\pi_d}(I_Q)}{R^*(I_Q)},$$

where I_Q is a random stream of arrivals chosen according to any probability distribution Q , and π_d is any deterministic on-line algorithm. Basically, it shifts the search for the optimum from a pathwise search under both randomized and deterministic algorithms to a probability distribution on the stream of arrivals under deterministic algorithms (see Ref. 27 that provides a framework to prove bounds using the aforementioned principle). Lan *et al.* [20] build on the competitive ratio approach of Ball and Queyranne [19] to solve, among other things, for the case where the demand for each fare has known bounds.

Instead of using a competitive ratio criterion (equivalently a minimax relative regret) one can use other criteria such as the absolute minimax regret or the maximin criteria as defined in the previous section. As a matter of fact, for the multifare single-leg problem, Lan *et al.* [20] prove under an absolute minimax regret criterion that nested policies are again optimal. They propose a unified framework for the competitive ratio and the minimax absolute regret and prove that the absolute regret booking limits are more aggressive than those obtained through the competitive ratio criterion. Finally, Perakis and Roels [21] apply both a maximin and the absolute minimax criteria to a network revenue management problem where demand belongs to a polyhedral uncertainty set (generalizing the single-leg model in Ref. 20). In this more complex setting, they restrict their attention to a set of control policies that include the nested booking limits and develop robust formulations.

SUMMARY

In this article, we have reviewed a representative model of revenue management and discussed different methods to deal with incomplete demand information. Each method depends on the specific context and the level of information available. Parametric models open the way for active learning approaches in which demand realizations are used to update estimates of the unknown parameters over time. These estimates are generally embedded within a dynamic programming formulation. The solution of the DP characterizes the pricing policy to adopt. Nonparametric models are less tractable. A first method that we discussed is based on the idea of replacing the demand uncertainty by a stochastic game using a maximin approach. In order to reduce the conservatism of this formulation, robust optimization is used limiting the feasible set. Eventually, the pricing policy is obtained by solving a complex ODE. An alternative nonparametric model uses passive learning during a specified interval of time, followed by a fixed-price policy for the remaining of the horizon. The pricing solution is simple to implement and asymptotically optimal. We finally discussed the competitive ratio criteria applied to the setting of a capacity allocation revenue management problem and compared that to the other robust criteria available in the literature.

REVENUE MANAGEMENT

GUILLERMO GALLEGO
IEOR, Columbia University, New
York, New York

INTRODUCTION

Revenue Management (RM) refers to techniques to optimally or near-optimally allocate capacity among different fare classes to maximize expected revenues from perishable resources. RM originated in the airline industry but its use has spread to hotels, car rentals, restaurants and other industries. In the airline industry, the resources are the seats in the airline network. There may be several fares associated with a flight itinerary. A fare is a combination of a price and a set of restrictions such as advance purchase, Saturday night stay, and limited seat selection. This is in essence service versioning where the quality of the service is modified to allow sales to multiple market segments at different prices. Allocation capacity among fares is difficult because demands are random and the allocation to lower fares often needs to be done before observing demand for higher fares. In addition, the very realization of demand depends on the capacity allocation policy. This is because as fares are closed, customer demand may shift to other fares or may be lost. Cancellations and no-shows complicate the problem and are mitigated by the careful and systematic use of capacity overbooking. Excellent books on the subject include Talluri and van Ryzin [1] and Phillips [2]. Previous surveys include McGill and van Ryzin [3], Bitran and Caldentey [4], and Elmaghraby and Keskinocak [5]. The aim of this article is to provide a brief and updated synthesis of RM covering both, single resource and network models and both independent and dependent demands. The article also provides suggestions for research at a more strategic level to help expand the practice of RM to other industries. Due to space

limitations, overbooking and forecasting are not covered. We refer the readers to the corresponding chapters in Talluri and van Ryzin [1] and Phillips [2] for these important topics. The article is organized as follows: the section titled “Single Resource RM with Independent Demands” covers the single resource problem with independent demands; the section titled “Network RM with Independent Demands” covers network models with independent demands; the section titled “Network RM with Discrete Choice Models” covers network models under discrete choice models, and the section titled “The Future of Revenue Management” provides suggestions for future research.

SINGLE RESOURCE RM WITH INDEPENDENT DEMANDS

We assume that the capacity provider has c units of perishable capacity of a single resource, such as seats on a specific flight, to be sold using n differentiated fares. More precisely, we assume n fixed fares $p_n < \dots < p_1$ with lower fares having more severe purchasing and traveling restrictions. Given the advance purchase restrictions associated with low fares, it is natural to assume that demand for fare classes arrive in a low-to-high pattern with fare class n arriving first, followed by $n - 1$, with fare class 1 arriving last. Let D_j denote the random demand for fare class j with finite mean $\mu_j = E[D_j]$. We assume that capacity provider is risk-neutral, and her objective is to allocate capacity among fares to maximize expected revenues. We assume that $D_1, \dots, D_n$ are independent random variables for the given fares. The independence assumption is approximately valid in situations where fares are well spread and there are alternative sources of capacity. A customer who finds that his/her preferred fare is unavailable, perhaps because the provider closed down the fare, is more likely to buy a similar fare from a competitor than to buy the next higher fare. The case

of dependent demands, where fare closures may result in demand recapture, is the subject of much active research and will be covered later in this article.

Given that low fares book first, it is important to decide how many units of capacity to reserve for later higher fare bookings. This is best done using dynamic programming (DP). Let $V_j(x)$ denote the maximum expected revenue that can be obtained from $x \in \{0, 1, \dots, c\}$ units of capacity from fare classes $\{j, \dots, 1\}$. The sequence of events for stage j are as follows: (i) observe the remaining inventory x ; (ii) decide the protection level, say $y \leq x$, for fares $\{j-1, j-2, \dots, 1\}$, leaving $x-y$ units available for sale at fare j ; (iii) D_j occurs, resulting in sales $\min(D_j, x-y)$ and revenue $p_j \min(D_j, x-y)$; and (iv) proceed to stage $j-1$ with capacity $\max(x-D_j, y)$.

Let $W_j(y, x) = p_j E \min(D_j, x-y) + EV_{j-1}(\max(x-D_j, y))$ and consider the DP recursion

$$V_j(x) = \max_{y \leq x} W_j(y, x). \quad (1)$$

The recursion can be started with $V_0(x) = 0, x \geq 0$ or with $V_1(x) = p_1 E \min(D_1, x)$ for $x \geq 0$ since it is optimal to make all the remaining capacity available for sale at p_1 . Assuming discrete distributions, the computational requirement to solve the DP for n stages is of order $O(nc^2)$. One can, in the process of solving the dynamic program, find an optimal policy that is, for every stage j , record for each x the largest protection level y maximizing Equation (1).

An optimal protection policy for fares $\{j, \dots, 1\}$ is a function, say $y_j(x) \leq x$, determining how many units of capacity to protect for each $x \in \{1, \dots, c\}$. Fortunately, an optimal can be characterized by a single critical protection level y_j^* such that $y_j(x) = \min(x, y_j^*)$ for each $j = 1, \dots, n-1$. It helps to think of y_j^* as the desired protection level for fares $\{j, \dots, 1\}$, so if $x \geq y_j^*$ then $y_j(x) = y_j^*$ units are protected and if $x < y_j^*$ then all $x = y_j(x)$ units are protected. Moreover, the critical integers y_j^* can be selected so that they are nondecreasing in j .

The key to the establishment of the form of the optimal policy and the determination of the critical protection levels is through

marginal analysis. For $y \in \mathcal{N}_+ = \{1, 2, \dots\}$ let $\Delta V_j(y) = V_j(y) - V_j(y-1)$, denote the marginal value of the y th unit of capacity at stage $j = 1, \dots, n$. It is possible to show that $\Delta V_j(y)$ is decreasing in y and increasing in j and that

$$\begin{aligned} \Delta W_j(y, x) &= W_j(y, x) - W_j(y-1, x) \\ &= [\Delta V_{j-1}(y) - p_j] Pr(D_j > x-y), \end{aligned}$$

for all $y \in \{1, \dots, x\}$. This implies that $W_j(y, x)$ is nondecreasing on $\Delta V_{j-1}(y) > p_j$ and nonincreasing on $\Delta V_{j-1}(y) \leq p_j$.

Let

$$\begin{aligned} y_j^* &= \max \{y \in \mathcal{N}_+ : \Delta V_j(y) > p_{j+1}\}, \\ j &= 1, 2, \dots, n-1, \end{aligned} \quad (2)$$

where y_j^* is set to zero if the set is empty. Notice that y_j^* is independent of demands $D_k, k > j$. It follows that at stage j , when we are maximizing $W_j(y, x)$ subject to $y \leq x$, we should select $y = \min(y_{j-1}^*, x)$. Indeed, if $x \leq y_{j-1}^*$ then $W_j(y, x)$ is nondecreasing in y up to x and if $x > y_{j-1}^*$ then $W_j(y, x)$ is nondecreasing up to y_{j-1}^* and nonincreasing beyond y_{j-1}^* . Moreover, it follows that $y_j^* \geq y_{j-1}^*$ since $\Delta V_j(y_{j-1}^*) \geq \Delta V_{j-1}(y_{j-1}^*) > p_j > p_{j+1}$ and $\Delta V_j(y)$ is decreasing in y . It is possible to relax the assumption that the fares are monotone $p_1 > p_2 > \dots > p_n$ but continue to assume that demands arrive sequentially in the order $D_n, D_{n-1}, \dots, D_1$. The dynamic program is unchanged, but there are some additional insights that can be gleaned. In particular, the monotonicity of the protection levels no longer holds as it is possible to show that $y_{j-1} = 0$ whenever $p_j > \max(p_1, \dots, p_{j-1})$. Dynamic programs for the multifare problem were developed independently by Brumelle and McGill [6] and Wollmer [7], with refinements by Robinson [8] who allows for nonmonotonic fares and proposes a Monte Carlo simulation approach to determining booking limits. van Ryzin and McGill [9] exploit the structure in Brumelle and McGill [6] to propose a method for setting protection levels that do not require forecasting or optimization.

Example 1. Suppose capacity is 50 and there are four fares $p_1 = 100, p_2 = 90$,

$p_3 = 80, p_4 = 70$ with independent Poisson demands with parameters $\lambda_1 = 10, \lambda_2 = 15, \lambda_3 = 25$, and $\lambda_4 = 15$. The optimal protection levels are $y_1 = 6, y_2 = 20$, and $y_3 = 44$. To see how the policy works assume that realization of demands for the four fares turn out to be $(d_4, d_3, d_2, d_1) = (13, 23, 14, 12)$. Since $c = 50$, and $y_3 = 44$, only 6 units of capacity are available to fare 4, so 4 units are sold at this fare, with residual capacity now at 44. Since $y_2 = 20$, we are allowed to book up to 24 units at fare 3, and since the demand for fare 3 is 23 we accept them all. Our residual capacity is now 21. Since we protect 6 units for fare 1, we allow up to 15 units to book at fare 2. Since the fare 2 demand is 14 we also accept them all. The residual capacity now drops to 7 and since demand for fare 1 is 12 we sell 7 units at fare 1.

Littlewood's Rule and Commonly Used Heuristics

For $n = 2$, $\Delta V_1(y) = p_1 Pr(D_1 \geq y)$ implying that

$$y_1^* = \max \{y \in \mathcal{N}_+ : p_1 Pr(D_1 \geq y) > p_2\}, \quad (3)$$

where y_1^* is set to zero if the set is empty. This is known as Littlewood's rule, [10], and it protects capacity for sale at fare p_1 as long as the marginal value exceeds p_2 . Several heuristics based on Littlewood's formula for the multifare problem were developed in the late 1980s before an optimal policy based on DP was discovered in the 1990s. For a while, some of these heuristics were thought to be optimal by some people. The heuristics are easy to understand and to compute so they were readily coded and embedded in RM systems. To this day, heuristics remain widely used, as they perform very well resulting in expected revenues that are very close to optimal. The two most popular heuristics are based on different versions of what is called the expected marginal seat revenue (EMSR).

Version *a* of the heuristic, EMSR-a, is based on the idea of adding protection levels produced by applying Littlewood's rule to successive pairs of fare classes. More precisely, $y_j^a = \sum_{k=1}^j y_{k,j}$ units are

protected for fares $\{j, \dots, 1\}$ where $y_{k,j} = \max\{y \in \mathcal{N} : p_k Pr(D_k \geq y) > p_{j+1}\}$. Version *b* is based on a single call to Littlewood's rule. To find the protection level for fares $\{j, \dots, 1\}$, aggregate demands $D[1, j] = \sum_{k=1}^j D_k$, use the weighted average fare $\bar{p}_j = \sum_{k=1}^j p_k \mu_k / \mu[1, j]$, where $\mu[1, j] = \sum_{k=1}^j \mu_k$, and apply Littlewood's rule to obtain $y_j^b = \max\{y \in \mathcal{N} : \bar{p}_j Pr(D[1, j] \geq y) > p_{j+1}\}$. Both of these heuristics perform very well with losses, relative to the DP solution, that are rarely above 0.5%, but EMSR-b is more commonly used. These heuristics were first published by Belobaba [11,12], but were probably used earlier at American Airlines.

Upper and Lower Bounds on the Value Function

It is sometimes useful to have bounds on the optimal expected revenue $V_n(c)$ as bounds are often used in revenue opportunity models (ROMs) developed for the purpose of assessing how well a given RM system performs relative to a readily computable upper bound. Consider the perfect foresight problem where the demand vector $D = (D_1, \dots, D_n)$ is known in advance. Perfect foresight allows us to optimally allocate capacity by solving a knapsack problem where x_k represents the capacity allocated to fare class k :

$$\begin{aligned} V_n(c, D) &= \max \sum_{k=1}^n p_k x_k, \\ \text{s.t. } x_k &\leq D_k \quad \forall \quad k = 1, \dots, n \\ \sum_{k=1}^n x_k &\leq c \\ x_k &\geq 0 \quad \forall \quad k = 1, \dots, n. \end{aligned} \quad (4)$$

The solution to Equation (4) is given by $x_k(D) = \min(D_k, (c - D[1, k-1])^+)$, $k = 1, \dots, n$ and corresponds to having fares arrive high-to-low with zero protection levels for lower fares. A little algebra shows that

$$V_n(c, D) = \sum_{k=1}^n (p_k - p_{k+1}) \min(D[1, k], c),$$

where for convenience we define $p_{n+1} = 0$. Because the allocations are done with perfect foresight, for every realization of D , $V_n(c, D)$

Table 1. Normal Demand Parameters and Protection Levels for Example 2

j	p_j	Demand Parameters		Protection Levels (y_j)		
		μ_j	σ_j	OPT	EMSR-a	EMSR-b
1	1050	17.3	5.8	9.7	9.8	9.8
2	950	45.1	15.0	54.0	50.4	53.2
3	699	39.6	13.2	98.2	91.6	96.8
4	520	34.0	11.3			

is at least as large as the revenue under the optimal dynamic policy for low-to-high arrivals. Thus, $V_n(c) \leq EV_n(c, D) \equiv V_n^h(c)$. Moreover, $V_n^h(c) \leq V_n(c, \mu)$, where $\mu = E[D]$, on account of Jensen's inequality and the fact that $V_n(c, D)$ is concave in D . The upper bound $V_n^h(c)$ is rarely computed, but it can be significantly sharper than $V_n(c, \mu)$ over a significant range of c values. A lower bound can be obtained by assuming a low-to-high arrival pattern with zero protection levels. This gives rise to sales $\min(D_k, (c - D[k+1, n])^+)$ at fare $k = 1, \dots, n$ and expected revenue

$$V_n^l(c) = \sum_{k=1}^n (p_k - p_{k-1}) E \min(D[k, n], c),$$

where for convenience we define $p_0 = 0$. In summary, $V_n^l(c) \leq V_n(c) \leq V_n^h(c) \leq V_n(c, \mu)$.

Example 2 [From Wollmer [7]]. There are four classes and the demand is assumed to be normally distributed. Table 1 shows the demand data and the protection levels under optimal, EMSR-a, and EMSR-b policies. The expected revenues of the optimal policy and the suboptimality gaps of the heuristics were estimated through a simulation study with 500,000 replications. The results are shown in Table 2 where we also include the bounds on $V_n(c)$.

All of the models reviewed so far treat time implicitly through the stages associated with different fare bookings. Significant work has also been done for single-resource problems where time is modeled explicitly; see Lee and Hersh [13], Feng and Gallego [14,15],

Feng and Xiao [16], and Weng and Zheng [17] for research involving the optimal time to switch between fares. See also Bitran and Mondschein [18] and Gallego and van Ryzin [19] for the related dynamic pricing problem where the price menu is not set in advance.

NETWORK RM WITH INDEPENDENT DEMANDS

Consider a network with several resources that can be combined in different ways to produce different products. In the context of an airline, the resources are the flight legs that are combined to form itineraries or routes from an origin to a destination. An origin-destination fare (ODF) represents an itinerary and a fare, so there may be many different fares corresponding to an itinerary with lower fares often being more restricted. Suppose that there are m resources in the network and let $c \in \mathbb{Z}^m$ denote the vector of initial capacities. We will assume that resources cannot be replenished during the sales horizon. Unlike the single-resource case, where time was modeled implicitly, we model time explicitly for network models. We will measure time backwards, so t will represent the time-to-go. Initially, $t = T$ and at the date of departure $t = 0$. For any time-to-go t we will let (t, x) represent the state of the system where x represents the vector of remaining inventories. The initial state is (T, c) . Let $V(t, x)$ denote the maximum expected revenue from state (t, x) . The main goal is to determine optimal or near-optimal admission control policies that tells us which ODF to accept at state (t, x) . Other goals may include computing $V(T, c)$ itself, or bounds and approximations on $V(T, c)$. We will assume that there are K itineraries, also known as origin destinations (ODs) and for each OD $k \in \{1, \dots, K\}$ there are n_k ODFs: $p_{k1} > p_{k2} > \dots > p_{kn_k}$. Corresponding to each of these fares there is a time-dependent arrival rate λ_{tkj} , so demand for fare p_{kj} over $[0, t]$ is Poisson with parameter $\int_0^t \lambda_{skj} ds$. Let A_k be the vector of resources utilized by OD k . Then A_k is an m -dimensional vector that corresponds to OD k . In the context of an airline, A_k is a vector of zeros and ones with

a one for each resource consumed by OD k . Consider now a time increment δt that is small enough so that we can think of $\lambda_{tkj}\delta t$ as the probability that an arrival occurs at time t for ODF kj . Then,

$$\begin{aligned}
V(t, x) &= \sum_{k=1}^K \sum_{j=1}^{n_k} \lambda_{tkj} \delta t \max\{V(t - \delta t, x), p_{kj} \\
&\quad + V(t - \delta t, x - A_k)\} + \left(1 - \sum_{k=1}^K \sum_{j=1}^{n_k} \lambda_{tkj} \delta t\right) \\
&\quad \times V(t - \delta t, x) + o(\delta t),
\end{aligned}$$

where $o(\delta t)$ is a quantity that goes to zero faster than δt . A discrete-time dynamic program can be obtained by ignoring the $o(\delta)$ term. Rearranging and taking limits we obtain the partial differential equation

$$\frac{\partial V(t, x)}{\partial t} = \sum_{k=1}^K \sum_{j=1}^{n_k} \lambda_{tkj} [p_{kj} - \Delta_k V(t, x)]^+, \quad (5)$$

with boundary conditions $V(t, 0) = V(0, x) = 0$ for all $x \geq 0$. Here $\Delta_k V(t, x) = V(t, x) - V(t, x - A_k)$ if $x \geq A_k$. Formulation (5) indicates that the marginal value of time is equal to the net revenue in excess of displacement costs. An optimal admission control rule at state (t, x) is to admit requests for which $p_{kj} \geq \Delta_k V(t, x)$, showing that if p_{kj} is admitted then so are all higher fares associated with OD k .

It is conceptually useful to think of $\lambda_{tk} = \sum_{j=1}^{n_k} \lambda_{tkj}$ as the arrival rate of requests for OD k and to write the arrival rates of specific

fares $\lambda_{tkj} = \lambda_{tk} q_{tkj}$ as thinned by probabilities q_{tkj} . This is equivalent to having random fare P_{tk} at time t for OD k , where P_{tk} takes value p_{kj} with probability q_{tkj} . Writing Equation (5) in terms of random fares yields the equivalent formulation

$$\frac{\partial V(t, x)}{\partial t} = \sum_{k=1}^K \lambda_{tk} E[P_{tk} - \Delta_k V(t, x)]^+. \quad (6)$$

Formulation (6) makes explicit the arrival rate for each itinerary and the fact that distribution of fares for an itinerary may change over time to reflect time preferences or fare restrictions. Formulation (6) is actually more general than the motivation that led to it as it is valid for any random fare P_{tk} with finite means. Viewing P_{tk} as a general random variable may be helpful to deal with net fares that depend on channel distribution costs. While formulation (6) is rich in detail, it is sometimes convenient to work with a more streamlined formulation that aggregates ODFs into a single index with $n = \sum_{k=1}^K n_k$ ODFs. Abusing notation slightly, the single index formulation results in

$$\frac{\partial V(t, x)}{\partial t} = \sum_{j=1}^n \lambda_{tj} (p_j - \Delta_j V(t, x))^+, \quad (7)$$

where in this formulation λ_{tj} and p_j denote respectively the arrival rate and the fare of ODF j . Note that in this formulation there may be multiple identical columns corresponding to different fare classes for the same OD. This formulation has the virtue of simplicity and generality at the cost of abstractness as it distances the model a little from its origins.

The simplicity of formulation (7) allows us to more easily treat the compound Poisson case, to discuss the nested-by-fare structure of optimal solutions and randomness in the arrival rates. If demand for an ODF j is a compound Poisson process with arrival rate λ_{tj} and demand size X_j with $q_j^l = P(X_j = l)$, then we can model this by using columns of the form $A_j^l = lA_j$ with corresponding fare p_j^l and arrival rate $\lambda_{tj}^l = \lambda_{tj}q_j^l$ for all l such that $q_j^l > 0$ and treating each column with corresponding fare and arrival rate as a different ODF with unit requests. This exercise essentially brings back the formulation to the Poisson case. Notice that the total fare p_j^l need not be lp_j thus allowing for economies or diseconomies of scale. Suppose ODFs j and j' consume the same vector of resources, that is $A_j = A_{j'}$ so that they represent the same itinerary but are sold at different fares, say $p_{j'} > p_j$. Then, since $\Delta_j V(t, x) = \Delta_{j'} V(t, x)$, $p_j \geq \Delta_j V(t, x)$ implies $p_{j'} > \Delta_{j'} V(t, x)$, so if it is optimal to accept ODF j it is also optimal to accept all higher fares for the same itinerary. Conversely, if $p_{j'}$ is rejected, then so are all ODFs for the same itinerary that carry a lower fare. If the arrival rates are random for each t , say λ_{tj}^i with probability θ_j^i , then the Hamilton–Jacobi–Bellman (HJB) equation (7) is of the same form with $\lambda_{tj} = \sum_i \lambda_{tj}^i \theta_j^i$.

The Deterministic Linear Program (DLP)

Formulations (6) and (7) are hard to solve. The quest to find good heuristics requires approximating the value function. The simplest approximation is the upper bound that emerges from the perfect foresight model for the network problem. Letting $\Lambda_{Tkj} = \int_0^T \lambda_{skj} ds$ denote the expected demand for ODF kj over the entire sales horizon $[0, T]$, we obtain a linear program whose value function is an upper bound on $V(T, c)$:

$$\begin{aligned} \bar{V}(T, c) = \max & \sum_{k=1}^K \sum_{j=1}^{n_k} p_{kj} y_{kj} \\ \text{subject to} & \sum_{k=1}^K A_k \sum_{j=1}^{n_k} y_{kj} \leq c, \\ & 0 \leq y_{kj} \leq \Lambda_{Tkj} \quad \forall \quad k, j. \end{aligned} \quad (8)$$

This formulation, due to Simpson [20], determines the number of units y_{kj} allocated to ODF kj subject to capacity and *expected* demand constraints. A proof that $\bar{V}(T, c)$ is indeed an upper bound can be found in Chen [21]. Since this problem is based on expected demands, it is known as the *deterministic linear program* (DLP) for RM. We will let $\bar{z}$ denote the vector of optimal dual variables to the capacity constraints.

Example 3. Consider a network with two connecting flights and assume that two fares are available for each individual flight, as well as for the connecting flight. Using the single index model we have 6 ODFs with incident matrix

$$A = \begin{pmatrix} 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix}.$$

The fare vector and arrival rates are as follows:

$$p = (150 \ 100 \ 120 \ 80 \ 250 \ 170),$$

$$\lambda_t = (0.06 \ 0.00 \ 0.04 \ 0.00 \ 0.06 \ 0.00),$$

$$0 < t \leq 500,$$

$$\lambda_t = (0.00 \ 0.12 \ 0.00 \ 0.16 \ 0.00 \ 0.08),$$

$$500 < t \leq 1000,$$

with capacity vector $c = (90, 90)$. Notice that the arrival rates are such that low fare demands arrive before high fare demands. The vector of $\Lambda_{Tj} = \int_0^T \lambda_{tj} dt$ of aggregate intensities is given by $\Lambda_T = (30 \ 60 \ 20 \ 80 \ 30 \ 40)$. The solution to Equation (8) is given by $\bar{y} = (30 \ 30 \ 20 \ 40 \ 30 \ 0)$, the vector of dual prices is given by $\bar{z} = (100, 80)$, and $\bar{V}(T, c) = \$20,600$.

Heuristics Derived from the DLP

Heuristics for the stochastic system can be constructed from solutions to the DLP and its dual. Any vector $z \in \mathbb{R}_+^m$ can be used to describe a *bid-price* heuristic admission control policy for the stochastic network RM problem. The heuristic works as follows: accept request for fare p_{kj} at state (t, x) if and only if $p_{kj} \geq z' A_k$ and $A_k \leq x$. In words, accept

a request if its fare equals or exceeds the sum of bid prices for the resources consumed and there is available capacity.

Talluri and van Ryzin [1] show that if the fares P_{tk} s in formulation (6) are *continuous* random variables that are *uniformly* bounded, then the bid-price heuristic based on $z = \bar{z}$ is asymptotically optimal as the capacity and the demands are scaled up by the same factor. This is an important result for systems that satisfy the stated conditions. In practice, the distribution of P_{tk} is often discrete and leads to both, fully accepted fares $F(p_{kj} > \bar{z}A_k)$ and partially accepted fares $P(p_{kj} = \bar{z}A_k)$. When partially accepted fares arrive before fully accepted fares, the heuristic may admit too many marginal fares. To illustrate this, consider the data of Example 3 and notice that $P = \{2, 4\}$ and $F = \{1, 3, 5\}$ with fares in P arriving before fares in F . The expected revenue of the bid-price heuristic, estimated via simulation, resulted in \$17,736.49 or 14% below the upper bound of \$20,600. This illustrates how bid-price heuristic without limits on marginal fares can cannibalize sales of higher, more profitable, fares.

To illustrate how the asymptotic optimality results fail in the case of discrete fares, consider the two-fare single-resource problem: $p_1 > p_2$, with expected demands $\Lambda_{T1} = (1 - \epsilon)c$ and $\Lambda_{T1} + \Lambda_{T2} > c$. Then $\bar{z} = p_2$ and the bid-price heuristic accepts all requests. If arrivals are low-to-high and $\Lambda_{T2} > \epsilon c$ then the entire capacity will be consumed by low-fare customers when in fact most of the capacity could have been sold at the high fare. One may try to correct things by redefining bid-price heuristics to accept fares only if $p_{kj} > \bar{z}A_k$. For our example, this is equivalent to accepting only fares in $F = \{1\}$, but then things go wrong if $\Lambda_{T1} = \epsilon c$ and $\Lambda_{T1} + \Lambda_{T2} > c$ as most of the capacity gets spoiled when in fact it could have been sold at the low fare. Note that neither version (accepting fares in $F \cup P$ nor F) of the bid-price heuristic improves as we consider scaled systems with capacity ac and aggregate demands $a\Lambda_{Tj}, j = 1, 2$, for values of $a > 1$.

There is fortunately an easy way to restore the asymptotic optimality by modifying the

admission control rule for ODFs in P . The modification is to accept ODFs in P with probability $\gamma_{kj} = \bar{y}_{kj}/\Lambda_{Tkj}$. Fares in F have $\gamma_{kj} = 1$ while fares in $R = \{kj : p_{kj} < \bar{z}A_k\}$ have $\gamma_{kj} = 0$. We will refer to this heuristic as the probabilistic acceptance rule (PAR) heuristic. It can be shown that the PAR heuristic is asymptotically optimal [22,23]. To see how the PAR heuristic works, consider again Example 3. Here we have $\gamma_2 = \gamma_4 = 0.5$. Modifying the heuristic to admit requests for these ODFs with probability 50% results in \$19,426.71 in expected revenues, estimated via simulation, compared to \$17,736.49 from the bid-price heuristic.

In practice, bid-price heuristics perform better if the DLP is resolved frequently during the horizon; for example, at reading dates when forecasts may also be updated. This helps because corrections can be made before too much of the demand is cannibalized by fares in P . Resolving the DLP has good asymptotic properties, see Maglaras and Meissner [24], in the context of a single resource. However, resolving may hurt rather than help performances in some instances; see Cooper [25] for details, particularly toward the end of the horizon when the fluid approximation implied by the DLP suffers the most from ignoring randomness. Resolving four times during the horizon in Example 3 improves expected revenues, estimated through simulation, to \$18,597.21 for the bid-price heuristic, and to \$19,561.88 for the PAR heuristic. Resolving ten times further improves expected revenues to \$19,792.74 and \$19,742.64, respectively, for the bid price and the PAR heuristics. Note that with frequent resolving, the bid-price heuristic does better than the PAR heuristic. This is not unusual as the bid-price heuristic tends to gradually tighten capacity for fares in P . Jasin and Kumar [26] show that using the PAR heuristic with sufficiently frequent resolving results in a *bounded* loss of optimality relative to $V(T, c)$.

Bid prices can also benefit from refinements that make them more sensitive to demand randomness. Talluri and van Ryzin [27] suggest repeatedly solving the DLP problem with simulated, rather than average, demands and then averaging the resulting

bid prices. Likewise, one can obtain average γ values for the probability of accepting requests for the PAR heuristic. Topaloglu [28] shows that randomizing the DLP preserves the asymptotic optimality properties in Talluri and van Ryzin [1]. Adding this refinement to Example 3 and resolving four times during the horizon results in estimated expected profits \$19,525.29 and \$19,406.08, respectively for the bid price and the PAR heuristic. Resolving ten times resulted in estimated expected profits \$19,658.77 and \$19,580.36. Note that while the refinement helped with four resolves, it did not with ten. This observation is consistent with other reports such as de Boer *et al.* [29] and Williamson [30].

Heuristics that Take Randomness into Account

Heuristic capacity allocation methods for ODFs in P that take demand randomness into account are often based on the EMSR-b heuristic. We will explain the most common form of this heuristic using the double index notation, let $F_k = \{kj : p_{kj} > \bar{z}'A_k\}$, $P_k = \{kj : p_{kj} = \bar{z}'A_k\}$ and $R_k = \{kj : p_{kj} < \bar{z}'A_k\}$. Let D_{kF} be a Poisson random variable with mean $\Lambda_{kF} = \sum_{j \in F_k} \Lambda_{kj}$ and let $\bar{p}_{kF} = \sum_{j \in F_k} p_{kj} \Lambda_{kj} / \Lambda_{kF}$. Now consider the itinerary $j \in P_k$ with the highest fare p_{kj} and apply an EMSR-b heuristic to find protection level y_{kF} for fare $\bar{p}_{kF}$ with Poisson demand Λ_{kF} against fare p_{kj} . This EMSR-b type analysis may be of help even for itineraries with $P_k = \emptyset$ by finding protection level y_{kF} for fares in F_k against the largest fare p_{kj} in R_k . Applying this idea to Example 3 results in booking limits 32, 42, and 3 for itineraries 2,4, and 6 respectively. Notice that even itinerary 6 which is rejected by the DLP gets some capacity under this scheme. The expected revenues for this heuristic, estimated via simulation, are \$19,641.80.

A more popular alternative is to use a resource decomposition approach by aggregating ODFs into buckets and to use EMSR-b or a similar heuristic for each resource. Using the single index model, let $I_j = \{i : A_{ij} > 0\}$ be the set of resources utilized by ODF j . The net contribution of ODF j to resource i is defined by subtracting from the fare the

value of the capacity used by ODF j on all other resources. For any vector of bid prices $z \geq 0$, let $p_{ij}(z) = p_j - \sum_{l \neq i} A_{lj} z_l$ if $i \in I_j$ and $p_{ij}(z) = 0$ otherwise. For each resource $i = 1, \dots, m$, we can now solve a single resource RM problem with fares $p_{ij}(z)$ and arrival rates $\lambda_{ij} = \lambda_j$ for all $j \in J_i = \{j : A_{ij} > 0\}$. Note that we no longer assume that the fares will arrive low-to-high, but a robust heuristic is used to compute protection levels as if the arrivals are low-to-high and then use standard, rather than theft nesting¹ [[31], p. 30]. The low-to-high protection levels can be computed using DP or a heuristic such as EMSR-b. If a mixed arrival model is used to compute protection levels, then it is important that it is implemented using theft, rather than standard, nesting. When a request for ODF j arrives at state (t, x) , the request is accepted if the net fare is accepted for each resource i such that $A_{ij} > 0$. The problem with a direct implementation of this approach is that there may be too many different itineraries mapped to resources. Some of these itineraries will have very similar net contributions and some will have very small demands. A natural idea is to aggregate the itineraries into buckets of similar net contributions and aggregate the demands within each bucket. This exercise results in more manageable single-resource allocation problems. This is known as displacement-adjusted virtual nesting (DAVN) [32] and combines ideas of bid prices and single-leg controls.

Consider Example 3 one more time and suppose that three buckets are defined such that bucket 1 contains all net fares greater than \$120, bucket 2 all fares between \$60 and \$120, and bucket 3 all fares below \$60. The itineraries that utilize resource 1, under the single index model, are 1,2,5, and 6 and the net fares for resource 1 are $p_{11}(\bar{z}) = 150$, $p_{12}(\bar{z}) = 100$, $p_{15}(\bar{z}) = 170 = 250 - 80$, $p_{16}(\bar{z}) = 90 = 170 - 80$. Accordingly, fares 1 and 5 belong to bucket 1, with corresponding expected demands 30 and

¹Under theft nesting bookings for higher fare classes, count against the booking limits of lower fare classes.

30. Fares 2 and 6 belong to bucket 2 with corresponding expected demands 60 and 40. We can aggregate fares 1 and 5 of bucket 1 into a single weighted average fare of 160 with aggregate demand 60. Similarly, for bucket 2 we can aggregate fares 2 and 6 into a single weighted average fare of 96 with aggregate demand 100. We can repeat the procedure for resource 2 and obtain net fares $p_{23}(\bar{z}) = 120$, $p_{24}(\bar{z}) = 80$, $p_{25}(\bar{z}) = 150$, and $p_{26}(\bar{z}) = 70$, with corresponding demands 20, 80, 30, and 40. Clearly, fares 3 and 5 map into bucket 1 while fares 4 and 6 map into bucket 2. We can aggregate fares 3 and 5 of bucket 1 into a single weighted average fare of 138 with aggregate demand 50. Similarly, for bucket 2 we can aggregate fares 4 and 6 into a single weighted average fare of 76.67 with aggregate demand 120. The expected revenues for this heuristic, estimated via simulation, are \$19,770.65. It is reasonable to expect even better performance with frequent resolving.

Dynamic Bid-Price Heuristics

A number of authors have developed more refined heuristics for the network RM problem. The main aim of these heuristics is to obtain bid prices that are responsive to changes in inventory and time-to-go. Adelman [33] proposes a heuristic based on approximate dynamic programming (ADP) with time-varying linear approximations. Bertsimas and Popescu [34] propose a heuristic based on accepting requests when the fare p_j exceeds the displacement cost $\bar{V}(t, x) - \bar{V}(t, x - A_j)$ generated from solving the DLP. One particularly successful heuristic is presented by Topaloglu [35] who proposes a Lagrangian relaxation (LR) approach to the network problem that decomposes the problem by flight, see also Talluri [36]. His method provides an approximation to the marginal value of each of the resources for every vector x of residual capacities at every time-to-go t . In his numerical study, Topaloglu reports significant improvements over a number of well-known heuristics including the bid-price heuristic based on the DLP and the refinements proposed by Adelman [33] and Bertsimas and Popescu [34]. The LR

heuristic is particularly good at exploiting time-varying arrival rates and in situations where there is a significant difference between adjacent fares. Data requirements, fare structures, and scalability are things to consider before implementing dynamic bid-price heuristics. If, for example, good estimates of time-varying arrival rates are not available and the fare structure is fairly dense, then the advantages of these methods may not justify the additional complexity.

Another stream of research tries to adjust bid prices and booking limits using simulation-based optimization, see Bertsimas and de Boer [37] who use simulation-based numerical approximations to first finite differences, to obtain improved booking limits. Their numerical studies show that their method improves booking limits generated either by the DLP or by the DAVN. As is usually the case, the advantage over more primitive methods diminishes with the number of times the system is resolved during the horizon.

NETWORK RM WITH DISCRETE-CHOICE MODELS

We now turn our attention to models that allow for dependent demands. In particular, we will be reviewing research based on discrete-choice models [38]. We will assume there are n different ODFs and there are L market segments. We will denote by $N_l \subset \{1, \dots, n\}$ the consideration set of ODFs that are of potential interest to customers in market segment $l \in \mathcal{L} = \{1, \dots, L\}$. At any state (t, x) , the set of ODFs offered for sale must be subsets $S_l \subset N_l, l \in \mathcal{L}$. If the consideration sets are nonoverlapping, that is, $N_l \cap N_{l'} = \emptyset$ for all $l' \neq l$, then there is no need to add further restrictions to the offered sets. This is also true even when consideration sets overlap, if the capacity provider is free to independently decide what fares to offer to each market. As an example, different fares are offered for round-trips from the United States to Asia depending on whether the customer buys the fare in the United States or in Asia. If the provider cannot make independent decisions by market segment then he

needs to post a single offer set $S \subset \{1, \dots, n\}$. In this case, market segment $l \in \mathcal{L}$ will have available fares in $S_l = S \cap N_l$. In addition, S_l customers arriving to market segment l have the no-purchase alternative so they are really selecting from the set S_{l+} that contains S_l and the no-purchase alternative for market segment l . We will follow tradition and abuse notation slightly and write $\pi_{lj}(S_l)$ where it would be more proper to write $\pi_{lj}(S_{l+})$ to denote the probability of selecting $j \in S_{l+}$ from market segment l with $\pi_{lj}(S_l) = 0$ if $j \notin S_{l+}$. One of the most commonly used discrete-choice models is the basic attraction model (BAM):

$$\pi_{lj}(S_l) = \frac{a_{lj}}{a_{l0} + \sum_{k \in S} a_{lk}} \quad j \in S_{l+}, \quad (9)$$

where a_{lk} is the attraction value of ODF $k \in N_l$ and a_{l0} is the attraction of the no-purchase alternative.

For ease of exposition we will assume that customers arrive to market segment l as a Poisson process with time-homogeneous rate λ_l . Let p_{lj} be the fare associated with $j \in N_l$ and let p_l be the vector with components $p_{lj}, j \in N_l$. We will denote by $V(t, x)$ the maximum expected revenues that can be obtained from state (t, x) where t is the time-to-go and x is the vector of remaining resource inventories. The HJB equation is given by

$$\begin{aligned} \frac{\partial V(t, x)}{\partial t} = & \sum_{l=1}^L \lambda_l \max_{S_l \subset N_l} \sum_{j \in S_l} \pi_{lj}(S_l) \\ & \times (p_{lj} - \Delta_{lj} V(t, x)), \end{aligned} \quad (10)$$

and $\Delta_{lj} V(t, x) = V(t, x) - V(t, x - A_{lj})$ if $A_{lj} \leq x$, and $\Delta_{lj} V(t, x) = \infty$ otherwise where A_{lj} is the j th column of the resource matrix A_l associated with market segment l , $j \in N_l$. Note that in this formulation all requests j in the offered set S_l are accepted as there is no positive part on the term $p_{lj} - \Delta_{lj} V(t, x)$. For this reason, the only candidate ODFs in an optimal set S_l are those such that $A_{lj} \leq x$. Talluri and van Ryzin [39] developed the first stochastic choice-based dependent demand model for the single-resource case in discrete time. The first network formulation in continuous time is due to Gallego *et al.* [40].

As in the independent demand case, the problem of solving the HJB equations (10) is intractable and for this reason, we resort to heuristics. As in the independent demand case, we can use the perfect foresight model to develop an upper bound by solving a linear program. Let $\lambda_l(S_l)$ be the n_l -dimensional vector with components $\lambda_l \pi_{lj}(S_l), j = 1, \dots, n_l$ and $r_l(S_l) = \lambda_l \sum_{j \in S_l} p_{lj} \pi_{lj}(S_l)$ be the revenue rate associated with the offer set S_l . Notice that we can write $r_l(S_l)$ as $p'_l \lambda_l(S_l)$. The decision variables will be for each market segment l the proportion of time, say $\alpha_l(S_l)$, during the sales horizon that we offer set $S_l \in \mathcal{N}_l$ where $\mathcal{N}_l$ is the collection of all subsets of N_l . The DLP will be called the choice-based linear program (CBLP). The first CBLP formulation appeared in Gallego *et al.* [40] who also show that the value function $\bar{V}(T, c)$ of the CBLP is an upper bound on $V(T, c)$. The formulation has $\sum_{l=1}^L 2^{n_l}$ variables $\alpha_l(S_l)$ representing the fraction of time set S_l is offered for market segment $l \in \mathcal{L}$ and is given by

$$\begin{aligned} \bar{V}(T, c) = & \max T \sum_{l=1}^L \sum_{S_l \in \mathcal{N}_l} r_l(S_l) \alpha_l(S_l) \\ \text{subject to } & T \sum_{l=1}^L A_l \sum_{S_l \in \mathcal{N}_l} \lambda_l(S_l) \alpha_l(S_l) \leq c; \\ & \sum_{S_l \in \mathcal{N}_l} \alpha_l(S_l) = 1, \quad l = 1, \dots, L; \\ & \alpha_l(S_l) \geq 0 \quad \forall \quad S_l \in \mathcal{N}_l, \\ & l = 1, \dots, L. \end{aligned} \quad (11)$$

For certain discrete-choice models, including the BAM, it is possible to efficiently use column generation to solve the CBLP to optimality. This line of attack was first used by Gallego *et al.* [40] and later by Liu and van Ryzin [41] and others to solve the CBLP for the case where each market segment can make independent decisions. Bront *et al.* [42] studied the problem with overlapping market segments and show that the column generation problem is NP-hard. Once the CBLP is solved, it is possible to apply a variety of heuristics.

Table 3. Data for Example 4

j	0	1	2	3	4	5
p_{1j}		800	700	650	600	550
a_{1j}	1.95	0.30	0.36	0.39	0.43	0.47
p_{2j}		400	375	360	340	225
a_{2j}	5.56	0.67	0.70	0.71	0.73	0.91
p_{3j}		1,000	900	800	700	600
a_{3j}	28.82	0.20	0.24	0.29	0.35	0.43

Example 4. Consider a network with two flights that connect to serve three markets: market 1 consists of the first flight, market 2 consists of the second flight, and market 3 consists of the two connecting flights with respective capacities 80 and 120. Demand for each of the three markets is driven by an Multinomial Logit (MNL) model. We will assume that the aggregate arrival rates for the three market segments are respectively $\lambda_1 T = 150$, $\lambda_2 T = 300$, $\lambda_3 T = 400$ where we select for convenience a timescale with $T = 1$. Each market has five fares and an outside alternative. In Table 3 we summarize the fares p_{lj} , and the attraction coefficients a_{lj} of the BAM for each market $l = 1, 2, 3$ and each fare $j = 1, \dots, 5$ with a_{l0} representing the attractiveness of the outside alternative for market segment $l = 1, 2, 3$.

Let $S_{lj} = \{lk : k \leq j\}$. Solving CBLP results in $\alpha_1(S_{14}) = 0.946$, $\alpha_1(S_{15}) = 0.054$, $\alpha_2(S_{24}) = 0.754$, $\alpha_2(S_{25}) = 0.246$, and $\alpha_3(S_{34}) = 1$, value function $\bar{V}(T, c) = \$94,064.63$ and dual vector $\bar{z} = (452.38, 152.84)$. Let F_{lk} denote the set of fares that is always offered and let P_{lk} denote the set of fares that are offered only part of the time. Then, $F_l = S_{l4}$ for $l = 1, 2, 3$, while fares $P_1 = \{15\}$, $P_2 = \{25\}$ and $P_3 = \emptyset$.

Heuristics Based on the CBLP

A bid-price heuristic based on the dual variables $\bar{z}$ of the capacity constraint would offer the set of fares $S_l = F_l \cup P_l = \{lj : p_{lj} \geq \bar{z}'A_l\}$ to market segment $l \in \mathcal{L}$. As with the bid-price heuristic for the independent demand model (IDM), this incurs the risk of admitting too many sales of marginal fares $P_l = \{lj : p_{lj} = \bar{z}'A_l\}$ that may cannibalize more profitable sales in the set $F_l = \{lj : p_{lj} > \bar{z}'A_l\}$. For

Example 4, the bid-price heuristic based on $\bar{z} = (452.38, 152.84)$ offers set $S_{15} \times S_{25} \times S_{34}$ while capacity is available, closing fares as capacity is exhausted. The expected revenues for this heuristic, estimated via simulation, are \$90,131.29. Frequent resolution helps mitigate this risk as the sets P_l then to shrink when the CBLP is resolved at reading dates. It is possible to show that a solution to the CBLP would be such that $\alpha_l(S_l) > 0$ only for subsets of the form $S_l = F_l \cup X_l$ with $X_l \subset P_l$. Given a solution $\alpha_l(S_l), l \in \mathcal{L}$ to the CBLP, the counterpart of the PAR heuristic would be to offer set S_l with probability $\alpha_l(S_l)$. The expected revenues for this heuristic, estimated via simulation, are \$90,020.27. Research by Jasin and Kumar [26] shows that applying the PAR heuristic with frequent resolves *bounds the difference* between the performance of the PAR heuristic and the value function $V(T, c)$, so PAR with frequent resolves is an asymptotically optimal heuristic.

Heuristics that Take Randomness into Account

It is possible, but difficult, to incorporate randomness into discrete-choice models. As in the IDM, most work in this area is in the context of the single-resource problem. Finding an effective procedure to solve this problem became a priority in the airline industry as competition from low-cost carriers forced airlines to redesign fares and to reduce fare restrictions. Belobaba and Weatherford [43] propose a variant of the expected marginal seat revenue (EMSR) formula that adjusts the fare ratio to take into account the probability that a customer would buy the next highest fare. While this formula provided a significant improvement over the unadjusted EMSR heuristic, there was plenty of opportunity for improvement as evidenced by refinements in Fiig *et al.* [44]. Brumelle *et al.* [45] develop a conditional probability formula for the two-fare problem with dependent demands. Their formula is in terms of conditional probabilities but no algorithm to actually compute protection levels as provided. Gallego *et al.* [46] provide a recursive procedure to numerically compute the conditional probabilities in Brumelle *et al.* [45] and obtain optimal protection levels. In addition,

they develop a heuristic that extends to the multifare problem. Numerical experiments show that their heuristic is close to optimal and performs significantly better than those developed in Belobaba and Weatherford [43] and Fiig *et al.* [44]. The heuristic provides protection levels for a set of fares against a larger set; for example, protection for fares $S_4 = \{1, \dots, 4\}$ against fares in $S_5 = \{1, \dots, 5\}$ suggests that fare 5 should be shut down when the remaining inventory falls down to or below the protection level. This is a form of *theft* nesting where fare 5 is closed down even after a certain number of bookings under S_5 even if those bookings happen to be for fares other than 5. It is possible to transform the protection levels and booking levels to work under standard nesting; see Talluri and van Ryzin [[31], p. 30], for a discussion of standard and theft nesting. As in the IDM, heuristics that take into account randomness can be applied judiciously to network models by projecting into resources or into itineraries.

Dynamic Bid-Price Heuristics

As with the IDM, it is possible to open the hood and work more closely with the value function to obtain refined heuristics. One of the first such heuristics was proposed by Liu and van Ryzin [41] who use the bid prices from the CBLP to net out fares for each resource. They then solve a netted-fare dynamic program for each resource. Armed with approximate value functions at the resource level, they develop a heuristic admission control rule and show that it is asymptotically optimal. Research by Kunnumkal and Topaloglu [47] goes further by using LR in an attempt to capture time-variant bid prices with good results. Zhang and Adelman [48] use ADP also in an attempt to capture time-variant bid prices. In addition, Zhang [49] uses a nonlinear and nonseparable functional approximation to the problem with good results. Chaneton and Vulcano [50] take a different approach and use simulation-based sample path gradients to construct a stochastic steepest ascent algorithm with impressive computational results. Caveats in terms of data requirements, fare distribution, and scalability are as valid here as in the IDM.

Generalized Attraction Model and Reformulation of CBLP

Most of the research for dependent demand models use a form of the BAM. Gallego *et al.* [51] introduced the generalized attraction model (GAM) where

$$\pi_{lj}(S_l) = \frac{a_{lj}}{a_{l0} + \sum_{k \in S_l} a_{lk} + \sum_{k \notin S_l} b_{lk}} \quad j \in S_{l+}, \quad (12)$$

and $b_{lk} \leq a_{lk}$ represents the attractiveness of purchasing product k from an alternative source. The b_{lk} s are discounted by the inconvenience cost and by the availability probability. The special case $b_{lk} = 0$ recovers the BAM, while the case $b_{lk} = a_{lk}$ recovers the IDM. The parsimonious model $b_{lk} = \theta a_{lk}$ for some $\theta \in [0, 1]$ can help test the hypothesis $H_o : \theta = 0$ or $H_o : \theta = 1$ against the obvious alternatives. Carefully fitting a GAM so that it performs well out of sample can help mitigate the upsell optimism of the BAM and the upsell pessimism of the IDM.

Gallego *et al.* [51] also present a sales-based linear program (SBLP) that is equivalent to the CBLP for discrete-choice models governed by the GAM. The advantage of this model is that it involves only $\sum_{l \in \mathcal{L}} (n_l + 1)$ variables instead of $\sum_{l \in \mathcal{L}} 2^{n_l}$ variables, where $n_l = |\mathcal{N}_l|$ is the cardinality of the consideration set of market segment $l \in \mathcal{L}$. This facilitates the development of more sophisticated heuristics as it now becomes practical to simulate aggregate demands for the market segments; solve the SBLP; and average the value function, the bid-price vector $\bar{z}$, and the admission probability vector γ to refine the upper bound, the bid-price heuristic, and the PAR heuristic.

THE FUTURE OF REVENUE MANAGEMENT

RM is likely to remain an interesting research topic both in terms of the development of new models and new algorithms. There is much work to be done to develop models with dependent demands including the study of correlations across products and across time; see Stefanescu [52]. Competition

has been an area that has seen lots of interest but can benefit from more research; see Gallego and Hu [53], Netessine and Shumsky [54], Perakis and Sood [55], and Xu and Hoop [56]. Forecasting under choice models with censored data is an important topic with ramifications to areas beyond RM; see Talluri [57] and Vulcano *et al.* [58]. Pricing and capacity allocation under demand uncertainty is yet another area that can benefit from future research and have broad impact; see Besbes and Zeevi [59] and Harrison *et al.* [60].

Most of the RM research done till date is at the operational level, with fares and restrictions taken as given. In practice, fares are designed with the purpose of versioning services, by imposing usage or purchasing restrictions, so they can be sold to different market segments at different prices. Effective fares coupled with RM allowed airlines and other industries to significantly improve their revenues with most of the improvements dropping directly to the bottom line. Over the last decade, however, the effectiveness of imposing fare restrictions has been eroded by internet fare transparency and in the case of the airline industry, by the presence of low-cost carriers.

At a more strategic level, we see two important challenges for RM. One is to find effective market segmentation tools. The other is to broaden RM to other industries. One could tinker with the idea of product versioning with the goal of improving ways of crimping services. However, versioning is but one tool to design and price derivative services to appeal to broader market segments and to improve resource utilization. As in financial engineering, it is possible to use options and bundling/unbundling ideas to modify a core service into derivative services; see Gallego and Stefanescu [61] and Gallego and Sahin [62]. These services help customers to manage consumption risk and capacity providers to broker flexibility among customers. Derivative services can be designed and priced to segment the market and benefit companies and their customers, but also to induce new demand from market segments that otherwise would not be interested in the company's offer. In

short, derivative services can help to improve demand management [63]. The engineering of derivative services is a strategic tool that can lead to significant increases in profits and market share in many industries including travel, leisure, hotel/hospitality, internet advertising, technology, transportation, supply chain, financial products and services, and club membership, among others.
